Abstract

Cytoskeleton is composed of more than 100 proteins and represents a dynamic network of the cellular cytoplasm. Cytoskeletal functions include spatial organization of cellular components, structural connection of the cell with external environment, and biomechanical force generation. Cytoskeleton takes part, at different levels, in all phases of platelet biogenesis: megakaryocyte (MK) differentiation, MK maturation, and platelet formation. In addition, it also plays a major role in each stage of platelet function. Inherited platelet disorders (IPDs) are a group of rare diseases featured by low platelet count and/or impaired platelet function. Over the past decade, the investigation of platelet biomechanics has become a major and highly relevant theme of research due to its implications at every stage of development of human life. The initial use of diverse biophysical techniques (e.g., micropipette aspiration, atomic force and scanning ion conductance microscopy, real-time deformability cytometry) started unraveling biomechanical features of platelets that are expected to provide new explanations for physiological and pathological mechanisms. Although the impact of cytoskeletal alterations has been largely elucidated in various IPDs' pathogenesis, the understanding of their impact on biomechanical properties of platelets represents an unmet need. Regarding IPDs, improving biomechanical studies seems promising for diagnostic and prognostic implications. Potentially, these characteristics of platelets may also be used for the prediction of bleeding risk. This review addresses the current available methods for biophysical investigations of platelets and the possible implementations in the field of IPDs.

Introduction

Cytoskeleton in Human Cells

Cytoskeleton is a dynamic network within the cellular cytoplasm composed of more than 100 constitutive and regulatory proteins.¹ The main classes of cytoskeletal polymers are micro-

tubules, representing the stiffest component, actin cytoskeleton, and the intermediate filaments. Microtubules and actin filaments are polarized proteins that facilitate movement of molecular motors such as myosin or dynein. Intermediate filaments, such as keratin and vimentin, interact with actin

cytoskeleton and microtubules forming structures that support cells to resist and respond to tensile forces or shear stress.²⁻⁴ The three principal functions of the cytoskeleton are (1) the spatial organization and trafficking of cellular contents, (2) the connection of the cell with the external environment at physical and biochemical levels, and (3) mechanotransduction and generation of biomechanical forces allowing the cell to move and modify its shape in response to stimuli. Thus, cytoskeleton plays a critical role in several key physiological and pathological processes, such as cell-shape maintenance, cell division, cell proliferation and migration, and tumor growth and progression. Our knowledge of cytoskeletal function at a molecular level is rapidly evolving, making its components even more precise disease biomarkers and possible therapeutic drug targets.^{2,5-7}

Specific alterations in cytoskeletal elements, or proteins connecting the cytoskeleton to the cell membrane, are responsible for diseases affecting different systems. For instance, in hereditary spherocytosis, mutations of spectrin and ankyrin hinder the biconcave shape maintenance of the red blood cells.⁸ Besides, anomalies of the intermediate filament nuclear lamin A/C represent the driving alterations of some genetic forms of dilated cardiomyopathy and muscular dystrophy.^{9,10}

Cytoskeleton in Platelets

Regarding cytoskeletal elements and their function/dysfunction, platelets share many similarities with other human cells but also several specificities. Cytoskeleton plays a major role both in platelet biogenesis and platelet function.¹¹⁻¹⁴ Mature platelets derive from bone marrow megakaryocytes (MKs), which release them in the blood stream at the end of a complex process driven by thrombopoietin.¹⁵ Throughout their maturation process, MKs undergo polyploidization by switching from mitosis to endomitosis while cytokinesis is inhibited. Soon after, MKs form large membrane reservoirs and eventually elongate proplatelets into the sinusoids of the vascular niche of the bone marrow.¹⁶ Platelet formation and shaping continues within the blood flow, passing through the intermediate form of “preplatelets.” Each of these processes is finely

regulated at the cytoskeletal level, particularly through the modulation of the cleavage furrow and the tuning of the structure of $\beta 1$ tubulin.^{12,17} Before proplatelets are released from MKs, microtubules reassemble to transport granules and organelles from the MK cell body to the forthcoming proplatelet tips.¹⁸ Not surprisingly, the cytoskeletal machinery also contributes to the final platelet dimension.^{19,20}

Although platelets participate in various processes beyond hemostasis, such as inflammation, innate immune response against bacterial pathogens, and interaction with tumor cells during cancer metastasis, their principal role is to safeguard vascular integrity.^{11,21-26} After adhesion to the damaged endothelium, integrin-dependent activation induces morphologic changes in platelets, which turn their original discoid shape to round to the peculiar “fried-egg” conformation.^{27,28} This process results in stronger platelet-extracellular matrix (ECM) adhesion, followed by platelet aggregation and eventually platelet contraction. The cytoskeletal framework takes part in all the aforementioned steps, at different levels (→Fig. 1).

Immediately upon exposure of subendothelial ECM proteins in a damaged vessel, low-affinity binding between platelet GP Ib-IX-V complex and von Willebrand Factor is established under shear. The consequential activation of this receptor complex, alongside that of G protein-coupled receptors, promotes a cytoskeleton-dependent rapid morphologic and functional transition of platelet integrins. Particularly GP IIb/IIIa, the most abundant platelet integrin, changes the conformation of its extracellular $\beta 3$ domain, thus increasing the affinity toward fibrinogen, fibronectin, and von Willebrand Factor. As a result, a stronger platelet adhesion to extracellular ligands via integrins is achieved.²⁹⁻³³

Cytoskeleton is at the crossroads of this process as it directly supports the adhesion-mediated morphological changes of integrins; at the same time, it senses the activated state of integrins and reacts by remodeling its structure to form filopodia and pseudopodia and initiates platelet contraction (→Fig. 2). The structural connectors between actin cytoskeleton and intracellular portions of integrins (e.g., β

Fig. 1 Schematic representation of subcortical cytoskeletal framework in platelets. The main structural components of the platelet cytoskeleton (e.g., actin filaments, microtubules, a motor protein such as kinesin, an actin-binding protein such as filamin) are depicted. Moreover, the structural link between cytoskeletal elements and transmembrane receptors (e.g., GP Ib-IX-V complex, G-protein-coupled receptors, GPCRs, Fc γ RIIIa, and integrin GP IIb/IIIa) is schematically illustrated.

Fig. 2 Cytoskeletal remodeling upon platelet activation and spreading. (A, B) Rapid morphological changes occur in platelets from the resting to the activated state involving adhesion and spreading on a planar adhesive substrate, visualized by scanning electron microscopy. (C–F) Remodeling of marginal tubulin band (green) and actin (magenta) is assessed by immunofluorescence microscopy (C, D) and transmission electron microscopy after removing of platelet membrane (E, F).

tail of GP IIb/IIIa) are diverse proteins such as filamin, myosin, and actinin- α -1.^{14,34}

Moreover, upon platelet activation, cytoskeleton microtubules disassemble, which maintains the discoid platelet shape in nonactivated platelets, and actin filaments assemble.^{35–37} Actin–myosin interactions, supported by the microtubule

architecture, drive platelet centripetal contraction and ensure the maintenance of platelet structure during spreading.^{38–40} Actin cytoskeleton also regulates the centralization of platelet organelles and the secretion of α - and dense granules.⁴¹ Finally, cytoskeleton-generated contractile forces are crucial during the late hemostatic phase of clot contraction.^{39,42}

Techniques for Biophysical Assessment of Platelet Biomechanics

Biomechanical properties of platelets, which are mainly contributed by the cytoskeleton, are increasingly recognized as highly relevant for platelet function.^{34,43} Alterations in biomechanical properties resulting in changes in contractility during adhesion-mediated spreading and intrinsic viscoelastic properties governing platelet deformation can potentially serve as label-free diagnostic markers of a pathophysiological state of blood platelets.^{44,45} A wide variety of biophysical techniques are currently used to assess cytoskeleton-dependent contractile force generation at piconewton (pN) and biomechanical properties of platelets at nanometer (nm) regimes.^{46–49} In this review we are focusing on micropipette aspiration, atomic force microscopy (AFM), scanning ion conductance microscopy (SICM), and real-time deformability cytometry (RT-DC) that offer varying degree of sensitivities and throughputs to investigate platelet biomechanics up to single platelets (–Table 1).

Micropipette Aspiration

Micropipette aspiration is one of the earliest biophysical approaches that were adopted for characterization of biomechanical properties of single platelets. It relies on the quantification of membrane deformation exerted by suction pressure applied through a borosilicate glass micropipette while the induced surface deformation is continuously

recorded in real-time by video microscopy.⁵⁰ In the field of platelets, White et al performed some of the earliest known biophysical measurements on single-platelet biomechanics and assessed the effect of microtubules and actin filaments on platelet deformation.⁵¹ From the perspective of clinical relevance, investigation of platelets from patients affected with Bernard–Soulier syndrome (BSS) provided interesting insights into the relations between platelet sizes and their capability to undergo deformation.⁵²

In addition, micropipette aspiration has been applied to evaluate the biomechanical changes induced by platelet agonists such as thrombin and ADP as well as antiplatelet drugs such as acetylsalicylic acid.^{53,54}

Atomic Force Microscopy

AFM is capable of providing a three-dimensional view of samples at nanometer (nm) scale and to investigate intermolecular and/or intercellular forces in the region of sub-pN. The main structural component is a long silicon nitride cantilever with a sharp tip at one end that is scanned over the sample on the *x*-, *y*-, and *z*-axis. It can be used both to scan the sample providing information about the size according to cantilever deflection, and to test its rigidity by applying force.⁵⁵ However, application of AFM to investigate platelets is a time-consuming and low-throughput technique and requires platelet immobilization. Despite these limitations, major findings on platelet biomechanics have been

demonstrated by AFM. Single-platelet elasticity module and areas at higher (e.g., edges) and lower (i.e., granulome) stiffness upon platelet adhesion have been established.⁵⁶ In addition, diverse adhesion forces produced by platelets adhering to different substrates (e.g., type 1 collagen, other platelets) according to their level of activation have been measured.⁵⁷

Currently, our laboratory is using a modified version of AFM called colloidal probe spectroscopy combined with confocal laser scanning microscopy. We have implemented this approach to investigate the biomechanical properties such as stiffness in addition to activation status of platelet aggregates generated under shear on different adhesive matrices (→Fig. 3). Although colloidal probe spectroscopy is similar to AFM in its basic functionality, instead of a sharp tip at the terminal end of the cantilever a micrometer-sized bead is immobilized (→Fig. 3A). In a typical colloidal probe experiment, the tip of the colloidal probe (i.e., microbead) is pushed gently against platelet aggregates by applying force in the order of a few nano newtons perpendicular to the horizontal plane of the platelet aggregate (→Fig. 3B). This results in deflection of the cantilever, which is representative of the resistive force of the platelet aggregates. This approach enables us to systematically characterize biomechanical properties of platelet aggregates formed on a wide array of adhesive matrixes, under different shear-stress conditions emulating vascular flow dynamics, its microenvironment, and local architecture (→Fig. 3C–E). Specifically, the contribution of nano-/microstructure of the exposed ECM and geometrical constraints affecting hemodynamics such as stenosis and blood vessel bifurcations on biomechanical properties of platelet aggregates can be assessed by this technique. We envision this approach will also be suitable for the assessment of effects of antiplatelet drugs, fibrinolytic and antifibrinolytic drugs on platelet function offering a mechanistic insight into biophysical parameters involved in these processes.

Scanning Ion Conductance Microscopy

As a complimentary approach to AFM, SICM represents a noninvasive, label-free high-resolution methodology for biomechanical measurements. SICM analyzes the sample by detecting ionic current perturbation induced by the characteristics of the specimen in response to hydrostatic pressure application.^{58,59} With this tool, relevant insights into elasticity variation occurring during platelet spreading have been investigated.⁶⁰ Moreover, the relationship between cytoskeleton remodeling and platelet stiffness upon thrombin-mediated platelet activation, or inhibition of actin polymerization, has been elucidated.⁶¹

Real-Time Deformability Cytometry

Most of the above-described biophysical methods used for biomechanical characterization of platelets are technically demanding and offer low throughput.⁶² To specifically address these issues, our laboratory has adopted a relatively easy-to-perform new technology called real-time deformability cytometry (RT-DC).⁶³ RT-DC combines the technique

of flow cytometry with label-free mechano-phenotyping (i.e., stiffness contributed by cytoskeleton) of cells using microfluidic laboratory-on-chip that is capable of reaching very high throughput of >1,000 single cells/second. In addition to determination of cell stiffness, RT-DC provides additional quantitative aspects related to cell size and morphometric parameters. This facilitates typifying a mixture of cells from peripheral blood by their size and simultaneously mechano-phenotyping these cells without prior separation, enrichment, and labeling procedures.^{64,65} To assess the effect of platelet cytoskeletal defects, recently Scheller et al using RT-DC have elegantly shown that platelets from mice lacking Coactosin-like 1 (Cot1) actin-binding protein were biomechanically softer and smaller in size in comparison to their wild-type counterparts.⁴⁵ In a latest technical development that is termed real-time 1D-imaging fluorescence and deformability cytometry (RT-FDC), it is possible to combine RT-DC measurements with fluorescence detection.⁶⁶ We have applied RT-FDC to assess platelet cytoskeletal-dependent biomechanical and size characteristics combined with the platelet activation marker CD62P (P-selectin) (→Fig. 4A, B). Using RT-FDC, we observed platelets upon stimulation with thrombin receptor activator peptide 6 (TRAP-6) become stiffer, undergo size reduction, and show CD62P expression. Surprisingly, platelets treated with cytochalasin D to block actin polymerization remained softer without undergoing significant size reduction while showing CD62P expression (→Fig. 4C, D).

Cytoskeleton Alterations in Inherited Platelet Disorders

Inherited platelet disorders (IPDs) are a group of rare diseases characterized by reduced platelet count and/or impaired platelet function causing variable bleeding tendency and, sometimes, other nonhematological findings that can be congenital or acquired.⁶⁷ In regard to pathogenesis, most of the authors have categorized IPDs according to the impaired phase of platelet biogenesis, namely MK differentiation, MK maturation, or platelet formation.^{68,69} The latter, which consists of proplatelet elongation by MKs and release of mature platelets in the flowing blood, can be peculiarly affected by mutations occurring specifically in cytoskeleton proteins or integrins involved in the connection of cytoskeleton and platelet membrane. The implication of cytoskeleton in the pathogenesis of IPDs has been more comprehensively addressed by some other dedicated reviews over the last few years.^{70–72}

In *MYH9*-related thrombocytopenia (*MYH9*-RD), one of the less rare forms of IPD, mutations affecting nonmuscular myosin IIA impair proplatelet formation leading to a delivery of a low number of enlarged platelets. In normal conditions, the interaction between MKs and bone-marrow ECM regulates the timing of platelet formation. Particularly, the binding of MKs with type 1 collagen, via $\alpha 2\beta 1$ integrin, leads to activation of Rho kinase ROCK that phosphorylates the regulatory chains of nonmuscular myosin IIA, thus preventing platelet release as long as MKs have reached the vascular niche of the bone marrow. In fact, *MYH9*-RD MKs also display premature and ectopic platelet release.^{73–75} The mutated

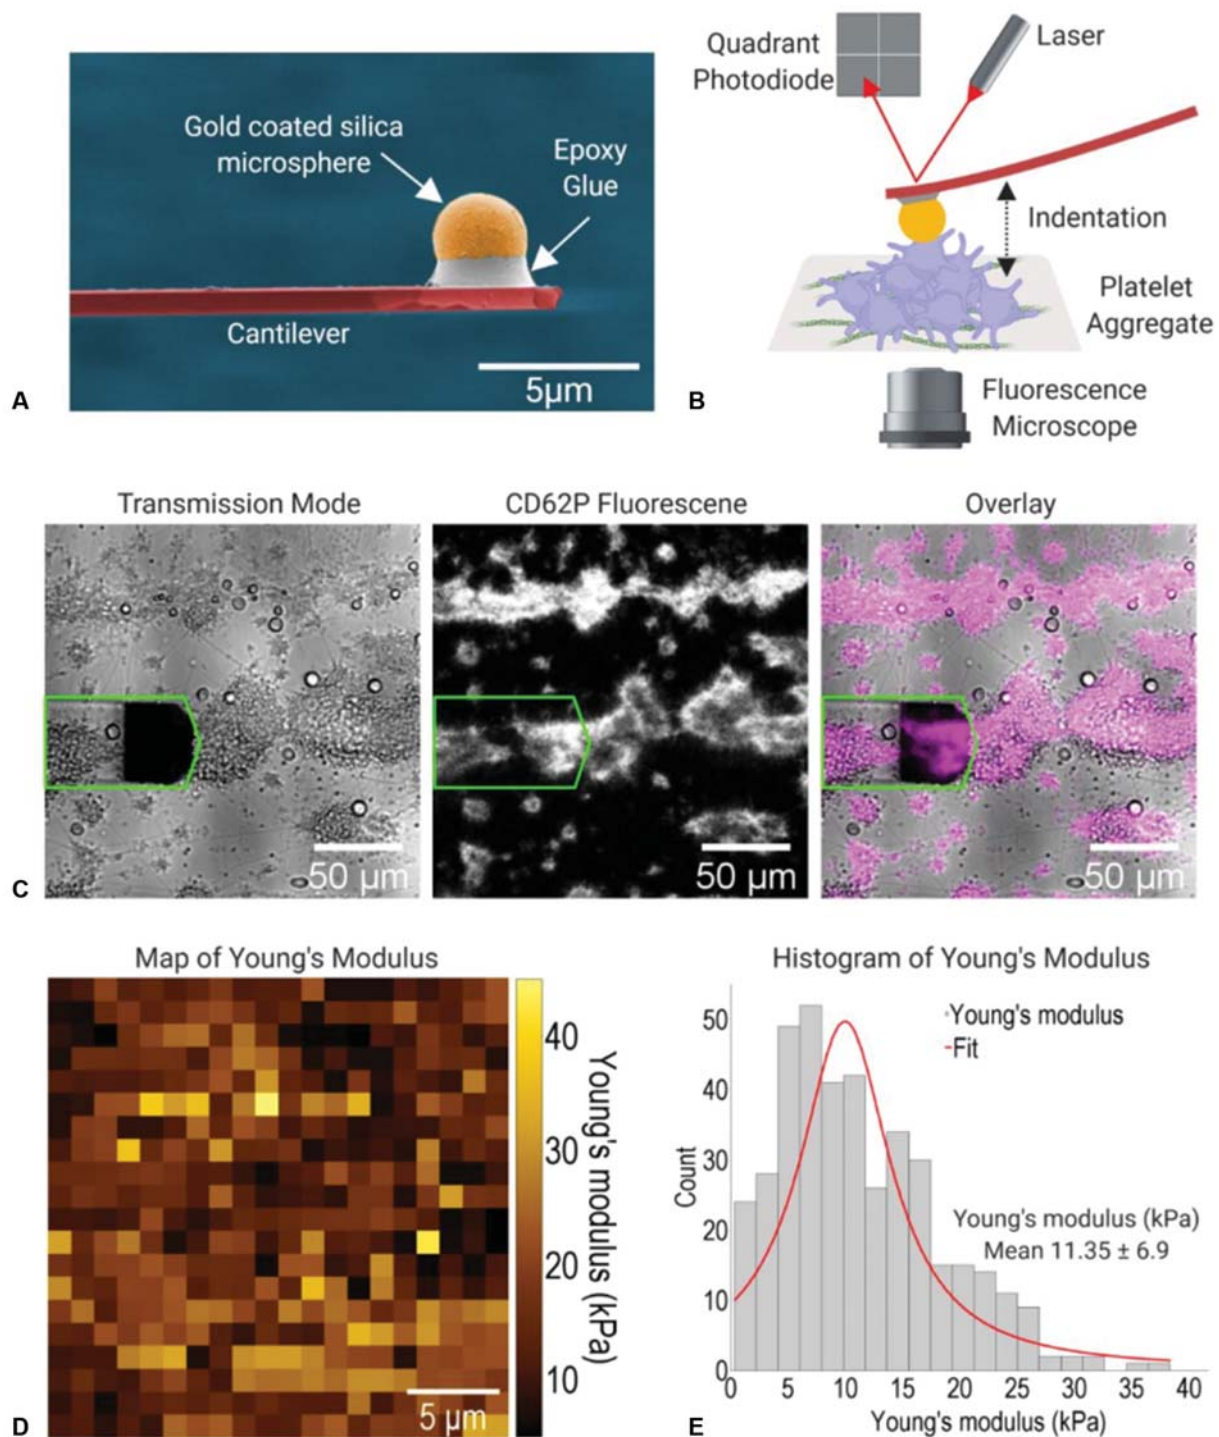

Fig. 3 Colloidal probe spectroscopy for biomechanical assessment of platelet aggregates. (A) Pseudocolored scanning electron micrograph of silicon nitride cantilever with a gold-coated microbead glued at its terminal end used for colloidal probe spectroscopy. (B) Similar to AFM, colloidal probe spectroscopy combines a sensitive octapoled piezoelectric transducer for x - y scanning, and an optical lever detection system for the analysis of the third dimension (the z -axis correlates to height movement in the piezo). The cantilever deflection is registered onto a quadrant photodiode from the reflected laser beam that provides a quantitative signal for the applied force as the colloidal probe is pushed against platelet aggregates, resulting in deflection of the cantilever according to the resistive force, F . According to this signal, F can be calculated based on the Hooke's law $F = -k \cdot d$, where k is the calibrated spring constant of the cantilever. (C) Different imaging modalities in an experimental setup using a combination of AFM and confocal laser scanning confocal microscopy. This allows identifying aggregates based on transmission, the fluorescence signal from activation status of platelets based on CD62P expression, and an overlay of the channels, allowing for an additional layer of useful information in combination with colloidal force spectroscopy. The green outline represents the cantilever above platelet aggregates formed under shear flow on a collagen substrate. (D) Representative 2D map of a platelet aggregate assessed by colloidal probe spectroscopy showing the map of Young's modulus (kPa) (i.e., biomechanical properties representing stiffness variations, see the look-up table on right) and (E) its distribution as a histogram. AFM, atomic force microscopy.

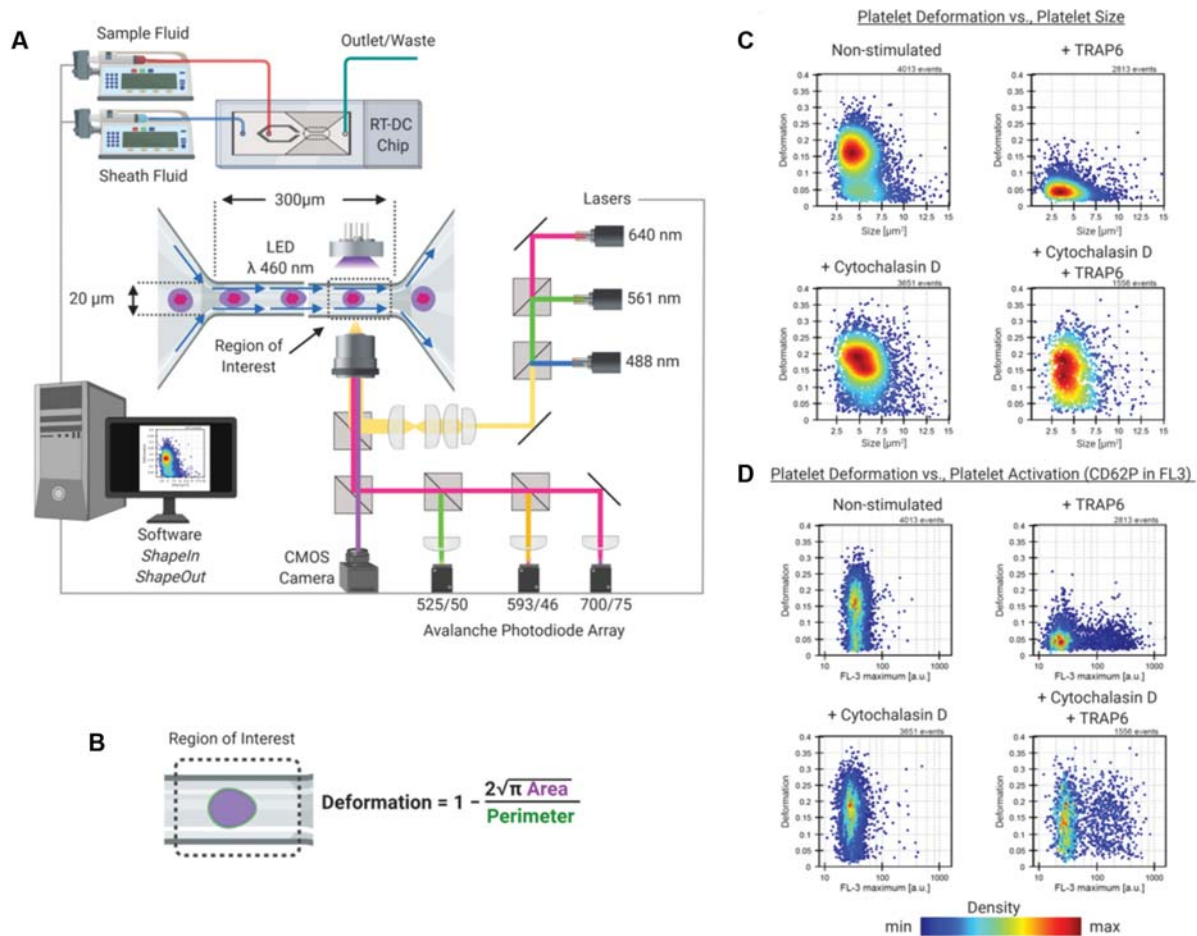

Fig. 4 Real-time 1D-imaging fluorescence and deformability cytometry (RT-FDC) as a biophysical tool for assessing single platelet biomechanics. (A) Schematic of RT-FDC setup showing a microfluidic chip connected to flow units with dedicated inlets for sheath fluid and for cells/platelets, which combine into a channel with narrow constriction zone where cell/platelets undergo deformation as a result of hydrodynamic compression brought about by sheath fluid. A high-powered light emitting diode (LED) illuminates platelets flowing through the narrow constriction zone. Images are registered by a scientific complementary metal–oxide–semiconductor (sCMOS) camera working at high frame rates ($\approx 2,000$ images/s) that is synchronized with the frequency of illumination time. This combined together with dedicated optical setup, excitation lasers of different wave lengths, and avalanche photodiodes for fluorescence detection working in sync with camera allows for simultaneous mechano-phenotyping and detection of activation markers of $>1,000$ platelets per second. (B) Platelet deformation (i.e., cytoskeleton-dependent biomechanical properties governing stiffness) is determined on the fly in real time by computational image processing algorithm that takes into account the area and perimeter of the deformed platelet as it passes through the region of interest. (C, D) Representative results of a typical RT-FDC measurement showing unstimulated platelets deform more (i.e., softer) while those treated with agonist (TRAP-6) deform less (i.e., stiffer) while expressing activation marker CD62P. Whereas, platelets preincubated with cytochalasin D lead to increased deformation (i.e., softer) and in combination with TRAP-6 co-stimulation platelets remain softer while still being able to undergo activation. Data show density maps of deformation against area (μm^2) from $n \geq 1,500$ individual platelets from a single experiment.

nonmuscular myosin IIA forms aggregates of diverse number and dimension in the cytoplasm of neutrophils, which is already used as diagnostic criterion.⁷⁶

Wiskott–Aldrich syndrome (WAS) and X-linked thrombocytopenia, two IPDs featured by thrombocytopenia and mild-to-severe immunodeficiency, are caused by alterations in the WAS gene. The corresponding protein WAS regulates actin cytoskeleton. Even in this case, patients' MKs show ectopic release of platelets, which also present a small size and a reduced life span.^{77,78} The $\beta 1$ tubulin rings in WAS are much more rigid and stretched—or present in eight-shaped conformations.⁷⁹

Two others IPDs due to alterations in cytoskeletal components are *ACTN1*-related thrombocytopenia (*ACTN1*-RT) and *FLNA*-related thrombocytopenia (*FLNA*-RT).^{80,81} The mutat-

ed proteins $\alpha 1$ actinin and filamin A, respectively, interact with actin and take part in diverse functions of cytoskeleton as the maintenance of stability properties and anchoring to the membrane. While no typical morphological changes for *ACTN1*-RT have been identified, in *FLNA*-RT, affected subjects can be detected by double labeling against filamin A and $\beta 1$ tubulin; the former protein can be undetectable at all or, sometimes, show diffused distribution instead of a thick peripheral ring.⁸¹

Mutations in another key element of microtubule architecture, $\beta 1$ tubulin, cause *TUBB1*-related thrombocytopenia (*TUBB1*-RT). Also in this form, features of impaired proplatelet processing and platelet shedding have been reported.⁸² In *TUBB1*-RT $\beta 1$ tubulin, normally forming a peripheral ring structure, is disturbed.⁸³ These patients display enlarged

Fig. 5 Identification of *TUBB1*-related thrombocytopenia on a blood smear. (A) Marginal band $\beta 1$ tubulin in healthy control. (B) A “ball of yarn”-like distribution in a patient carrying a causative mutation in the *TUBB1* gene observed by confocal laser scanning immunofluorescence microscopy.

platelets in which $\beta 1$ tubulin resembles the appearance of a ball of yarn (→Fig. 5). Finally, in macro-thrombocytopenia due to a gain-of-function variant in *DIAPH1*, α -tubulin rings are also much more rigid and maintain their ring form when the blood is cooled down to 4°C, a condition under which normally microtubules disassemble.⁷⁷

Beyond binding to their specific extracellular ligands (e.g., von Willebrand Factor and fibrinogen), platelet receptor complex GP Ib-IX-V and integrin GP IIb/IIIa also stabilize the interaction between cytoskeleton and membrane. Alterations of this dynamic equilibrium can perturb proplatelet formation leading to ectopic and inefficient platelet production.⁶⁹ For instance, in regard to monoallelic BSS, the heterozygous c.515C > T transition in *GPIBA* gene (i.e., Bolzano mutation) drives a dominant form of macro-thrombocytopenia with defective proplatelet formation because of impaired cross-talking between plasma membrane and platelet cytoskeleton via the intracellular chain of GPIIb.⁸⁴ Conversely, gain-of-function mutations in *ITGA2B* or *ITGB3* (coding GPIIb and GPIIIa) cause a dominant variant of Glanzmann thrombasthenia with mild thrombocytopenia, large platelets, and constitutive activation of GP IIb/IIIa.⁸⁵ The impaired function of this integrin specifically triggers cytoskeleton remodeling and, in turn, alterations in the latest phase of platelet biogenesis.

Although the role of cytoskeleton has been largely elucidated in normal megakaryopoiesis and in the pathogenesis of some IPDs, much less is known about the possible impact of the reported cytoskeletal alterations on the biomechanical properties of platelets. Understanding the associated alterations of biomechanical consequences in IPDs represents an unmet need. It might be that changes in the biomechanical properties caused by IPDs could explain, for example, the variability of hemorrhagic diathesis observed in patients sharing similar levels of platelet counts and functional parameters as assessed by traditional tools. Moreover, since cytoskeletal elements represent possible pharmaceutical targets, unraveling biomechanical alteration of single or group of IPDs can lay the ground for the development of new therapeutic options to prevent and contrast bleeding symptoms in these patients.^{67,86}

Time Capsule

Key Advantages to Be Expected in 2050

- Super-resolution immunofluorescence microscopy will enable visualization of finer details of platelet cytoskeletal defects below diffraction limits, thus allowing a nanoscopic and mechanistic view of platelet function.
- Wider application of biophysical methods such as AFM and RT-DC will broaden our knowledge about underlying biomechanical principles affecting platelet cytoskeleton and their impact on platelet function.
- In the field of IPDs, the implementation of biomechanical investigations is anticipated to clarify pathogenic mechanisms of a relevant group of disorders, and to pave the way for a major role in diagnostic work-up and management.
- From a clinical point of view, the use of biomechanical assessment as point-of-care testing is expected to represent a key modality to stratify patients for bleeding (and thrombotic) risk, thus allowing tailored therapy and monitoring approaches. RT-DC, for the first time, allows such an approach with a high enough throughput suitable to clinical needs.
