Abstract

Glomus tumors are a mostly benign neoplasm that constitutes less than 4% of upper-limb soft-tissue tumors. Its unspecific clinical presentation, added to its low frequency, leads to a late diagnosis.

The objective of the present study is to update the clinical-paraclinical approach and the surgical technique used in the treatment.

We carried out a literature review from 2014 to 2019 on digital glomus tumor in the hand in adult patients using the PubMed search engine.

In most of the publications analyzed, the diagnosis was clinical, with a delay of 1 to 10 years. Plain radiography is the most requested study; of the 16 articles reporting its indication, only half evidenced compatible changes. Magnetic resonance imaging (MRI) was requested in 15 articles, presenting normal results in 3 of them. The treatment of choice was surgical excision using a transungual approach. Only 4 articles report recurrence after excision.

Although there is diversity in the approach to these tumors, we conclude that the diagnosis is clinical, and the treatment surgical, and there is no consensus regarding the paraclinical indication. The information available comes mainly from case reports, publications that contribute to the generation of evidence for the clinical practice in rare diseases such as this one.

- ▶ literature review as a topic

Resumen

El tumor glómico es una neoplasia en su mayoría benigna, que constituye menos del 4% de los tumores de tejidos blandos del miembro superior. Su presentación clínica inespecífica, sumada a su baja frecuencia, lleva a un diagnóstico tardío.

El objetivo del presente estudio es realizar una actualización sobre el abordaje clínico-paraclínico y la técnica quirúrgica utilizada en el tratamiento.

Realizamos una revisión bibliográfica desde 2014 a 2019 sobre tumor glómico digital en la mano en pacientes adultos utilizando el buscador PubMed.

El diagnóstico de tumor fue mayormente clínico, con un retraso desde 1 a 10 años. La radiografía simple es el estudio más solicitado; de los 16 artículos que informan su indicación, sólo la mitad evidenciaron cambios compatibles. La resonancia magnética (RM) se solicitó en 15 artículos, y presentó resultados normales en 3 de ellos. El tratamiento de elección fue la exéresis quirúrgica utilizando un abordaje transungueal. Solamente en cuatro artículos se reporta recidiva luego de la exéresis.

Palabras Clave

- ▶ tumor glómico
- ▶ dedos
- ▶ revisión de literatura como asunto

Si bien existe diversidad en el abordaje de estos tumores, concluimos que el diagnóstico es clínico y el tratamiento, quirúrgico, no existiendo consenso en cuanto a la indicación paraclínica. La información proviene principalmente de reportes de casos, publicaciones que contribuyen a generar evidencia para la práctica clínica en patologías poco frecuentes como esta.

Introduction

Glomus tumor is a cell proliferation originating from the glomus body, a contractile neuromyoarterial receptor located at the dermoepidermal junction that is responsible for regulating peripheral blood flow and temperature.¹ It was described by Wood² as a “painful subcutaneous tubercle” in 1812, and was renamed vascular hamartoma or neuromyoarterial hyperplasia in 1924, when Barre and Masson described its histology. Today, the term used in the literature is glomus tumor.

They represent 1% to 4% of upper-limb soft-tissue tumors, and are largely benign. They are more frequent among women aged between 40 and 50 years, in a 4:1 ratio when they are digital, and in a 3:1 ratio when they are extradigital.¹ In 75% of the cases, they tend to be located in the subungual area.^{3,4}

Clinically, they can manifest as a small, round tumor, rarely larger than 1 cm, presenting the classic triad of intense spontaneous pain, exquisite pain on palpation, and hypersensitivity to cold. They are characterized by presenting a positive result of the Love, Hildreth and pain tests when exposed to cold. In cases of subungual presentation, the tumor can be visible through the nail plate and even deform it.⁴ (▶ **Figure 1**).

However, the presentation without an evident tumor is frequent, which, added to its low frequency and the presence of nonspecific symptoms, contributes to the late diagnosis, with publications reporting more than 10 years of delay from the onset of symptoms to the diagnosis.⁵

The indication of the different imaging studies is controversial, and the importance of the clinical practice for the diagnosis and the indication of surgical treatment is accepted in the literature.^{1,6,7}

Given the variability of criteria regarding the approach to glomus tumors, the purpose of the present work is to describe the clinical presentation, the imaging studies requested, and the treatment chosen in international publications over the last 10 years.

Materials and Methods

We performed a literature review on glomus tumor on the fingers of the hand in adults. Using the Pubmed search engine,

we looked for articles published between January 2009 and June 2019 with the keywords: *glomus*, *tumor* and *finger*.

The abstracts of the articles found in the first search were analyzed by the authors, who selected the publications that met the following inclusion criteria: clinical trials, case series, case reports, and literature reviews that included patients aged 18 years or older with a diagnosis of glomus tumor and digital topography in the hand.

The exclusion criteria were: extradigital topography, main subject other than glomus tumor, and publications without an identifiable scientific article format.

All the articles were analyzed by the authors, who inserted the following data in a spreadsheet: general information on the work (main author, journal name, and year), characteristics of the work, clinical presentation, paraclinical examinations requested, surgical technique, evolution

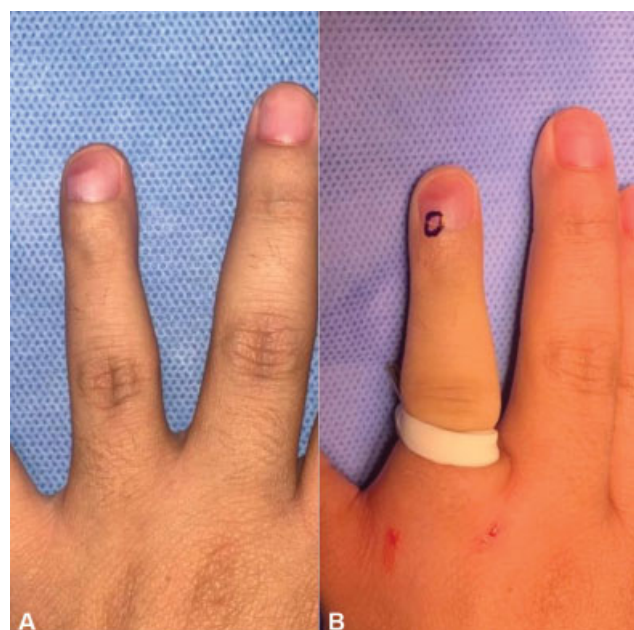

Fig. 1 (A) Clinical case showing nail deformity caused by a tumor. (B) Area of greatest pain on palpation.

(recurrence, complications), and presence of malignancy in the anatomopathological diagnosis.

The present work was carried out in accordance with the rules of the Ethics Committee of Hospital de Clínicas Dr. Manuel Quintela, Montevideo, Uruguay. The patients gave their informed consent regarding the publication of images featuring them.

Results

In the initial primary search, we retrieved a total of 59 articles. After applying the inclusion and exclusion criteria, we selected 30 publications to analyze: 22 were case reports,⁸⁻³⁰ 5 were retrospective cohorts,^{4,31-34} and 3 were case series.^{1,35,36}

The general data of the articles are presented in ►Table 1, and the clinical variables described below are summarized in ►Table 2.

Clinical diagnosis

Time until Diagnosis

Regarding the delay in diagnosis, defined as the time elapsed from the onset of symptoms to the definitive diagnosis, 22 articles mention this variable, with a maximum value of 50 years in 1 publication,⁹ and a minimum of 6 months in 2,^{12,15} although most of them (19 articles^{10,12,14-16,19-21,23-26,28-30,33,36,40}) refer to periods from 1 to 10 years.

Tumor Size

Regarding the clinical presentation as a tumor, 19 articles^{1,8-10,13-15,18,19,21,23,24,28,30,32-35,40} describe its size with a variability from 1.8 mm to 26 mm, with a predominance of 10 mm or smaller, reported in 17 articles.^{1,9,10,13-15,18,19,21,23,28,30,32-35,37}

Nail deformity

The initial clinical presentation with nail deformation is found in 15 articles,^{1,9,11,15,19,20,24-27,30,31,34-36} is specified as absent in 10, while 5 articles don't mention it.^{12,23,29,32,33}

Clinical Triad

The classic clinical triad was reported with all its components in most cases (16 articles): the most frequent symptom was spontaneous pain, found in 24 articles,^{1,8-10,12-16,18-23,25,26,28,29,32,35,36,40} while only El Jouari et al.²⁴ and Kallis et al.²⁷ specified the absence of this symptom in their case reports.

Regarding the exacerbation of pain on palpation or minimal contact, 21 articles^{1,8-12,14-16,18-21,25-29,32,36,37} refer to it as present at the time of diagnosis, and only El Jouari et al.²⁴ refer to the absence of this symptom.²⁴

Hypersensitivity to cold is present in most cases (17 articles^{1,8-10,12,14-16,19-21,23,25,26,32,36,40}); in 2 publications,^{18,24} it is reported as absent, while its presence or absence is not mentioned in the remaining articles.

The diagnosis of asymptomatic glomus tumor was reported by El Jouari et al.²⁴ in a male patient whose only pathology was a tumor with a 3-year progressive growth that produced nail deformity.

Love Test, Hildreth Test and Cold Immersion Test

Regarding the clinical tests for diagnosis, 20 articles report a positive Love test in 100% of the patients, 9 articles^{1,8-10,12,14-16,19-21,23,25,26,32,36,40} do not specify its performance, and only Jouari et al.²⁴ report negative results.

Regarding the Hildreth test, only 11 articles mention its performance, 9 of which report positivity in 100% of the cases.^{18-20,22,23,33,34,36,40}

The cold immersion test is reported as positive in 20 articles,^{1,8-12,14-16,19-21,23,25,26,28-30,32,36} and negative in 2.^{18,24}

Epidemiology

Regarding the distribution by gender, 65% of the cases occurred in female patients. In 17 articles,^{8-13,15,16,18-23,25-27} the case reported involved female patients, while 5^{14,24,28-30} publications only reported cases involving male patients. The average age of the patients was 47 years, ranging from 23 to 78 years.

Of the 30 articles included in the present review, 8 reported cases with topography on the index finger, 5, on the thumb, 5, on the ring finger, 5, on the little finger, and 3 articles^{14,26,28} referred to the third finger. The rest of the works did not specify the exact topography.

In 70% of the cases, the tumors were at the subungual level, while 20% were cases of volar glomus tumors. The remaining 10% of the studies reported cases of tumors at the level of the first, second or third phalange.

Image Studies

Plain radiography is the most requested study: 18 articles^{1,8,10,12,15,16,18,20-22,24,26,29,32,35,36,40} report its indication in the preoperative period; and, in 8^{1,8,15,22,26,32,35,37} of them, compatible radiographic changes are evident. The radiographic reports vary, and, in most cases, they are of bone erosion and dorsal deformity in the distal phalanx due to extrinsic compression, and in fewer cases, of soft tissue edema and scalloping with sclerotic edges.

Le Corroller et al.²² report a case of intraosseous glomus tumor in the middle phalanx, with particular radiographic findings such as a radiolucent image in the medullary and proximal epiphysis of the middle phalanx, with erosion of the endosteum of the adjacent cortical bone. The result of the X-ray was normal in the remaining eight articles.^{10,12,16,20,24,28,29,36}

Magnetic resonance imaging was performed in at least 1 of the patients in 15 articles.^{1,12,16,18-20,22,24-26,28-30,35,36} In general, the finding of a soft-tissue image hypointense in T1 and hyperintense in T2 was described,^{24-26,28,29} also presenting enhancement after contrast injection.^{24,25,28} Gandhi et al.,³⁶ in their series of 12 cases, included 1 patient who underwent MRI after a recurrence, using a 1.5-Tesla scanner with fine sections, without obtaining an image of the tumor. In 3 publications,^{16,20,30} the result was normal. Mitchell et al.¹⁸ report a case in which the MRI presented findings compatible with a tendon giant cell tumor, but, after excision, they confirmed it was a glomus tumor.

Regarding ultrasound, its use is mentioned in 6 articles.^{1,11,14,19,23,31} In the series of 33 cases with digital

Abbreviations: CR, case report; CS, case series; R, review; RC, retrospective cohort.

glomus tumor published by Chou et al.,¹ it was only performed in 2 cases, and the authors did not describe the findings. In the publications in which the result is detailed, it is generally described as a solid, hypoechoic, well-defined lesion, with regular borders, in some cases showing hypervascularization compared to Doppler ultrasound, which tells us about the vascular nature of the tumor.^{16,21,25}

Ultrasound was either not performed, or its performance was not reported, in 23 studies.^{4,8-10,12,14,15,18-20,23,24,26-30,32-34,36,40}

Treatment

Surgical Technique

Regarding the surgical approaches used, the transungual approach was used in 52% of the publications, the volar approach, in 35%, and the lateral subperiosteal, in 29%. Dominguez-Cruz et al.¹³ report one case of treatment using ultrasound-guided transungual punch.

Complications

The complication most frequently found was nail deformity,^{1,28} and, less frequently, hypoesthesia and hypertrophic scar.³³ No complications were reported in 16 articles.^{4,8-16,18-29,32-37}

Recurrence

Recurrence, was reported in 5 articles,^{1,13,19,32,34} with a frequency ranging from 0% to 100%.

Chou et al.¹ described a relapse rate of 3.03%; Lee et al.,³² of 6.6%, Lin et al.,³⁴ of 13%, and Domínguez-Cruz et al.¹³ and Chuang et al.,¹⁹ 100%. The latter¹⁹ performed the partial amputation of the distal phalanx in the presence of recurrence of an intraosseous glomus tumor.

Gandhi et al.³⁶ reported an initial recurrence in 41.6% of the patients, and a second recurrence in 25%.

In 19 articles,^{4,8-10,12,14,15,18-23,26,28,29,33,35,40} there was no recurrence after surgical excision.

Pathological Anatomy

Regarding the definitive diagnosis, in 28 articles,^{1,4,8-10,12-14,16,18-22,24-30,32-36,40} it was confirmed by pathological anatomy without describing the details of the analysis.

On microscopy, the presence of tumor proliferation made up of aggregates of monomorphic cells with round nuclei and eosinophilic cytoplasm surrounding vascular structures is characteristic of these tumors.

Kabukçuoğlu et al.²³ and Falletti et al.¹⁵ described a variant of symplastic glomus tumor, characterized by the presence of nuclear atypia in the absence of any other characteristic of malignancy.

None of the articles reported the presence of glomangiosarcoma, a malignant variant of glomus tumor.

Abbreviations: Negative, performed, and the result was normal; NP, not performed; NR, not reported; Positive, performed, and the result showed compatible changes.

The data extracted regarding the paraclinical, therapeutic, histology and evolution variables are shown in ► **Table 3**.

Discussion

The present review reflects the variety of clinical presentations and diagnostic algorithms, as well as the fact that most of the references come from case series.

Glomus tumors represent a pathology characterized by a late diagnosis, with multiple previous consultations mainly motivated by spontaneous and disabling pain after tactile or thermal stimuli. A classic triad of spontaneous pain, pain on minimal contact, and hypersensitivity to cold is described; combined, these symptoms increase the diagnostic precision.⁸ Some authors⁵ state that difficult-to-manage paroxysmal pain is pathognomonic for the diagnosis. Several hypotheses are suggested regarding the cause of pain in glomus tumors. The abundant mast cells in glomus tumors release substances such as heparin, 5-hydroxytryptamine, and histamine, which makes pressure or cold stimulation receptors sensitive even to a minor stimulus.^{32,38} In addition, it has been proposed as a cause the existence of numerous unmyelinated nerve fibers that penetrate glomus tumors and vasodilation of the Sucquet-Hoyer arteriovenous canals, which dilate in response to cold to avoid excessive heat loss in the fingers.²⁸ In our review, spontaneous pain was not reported only in 2 cases.^{24,27}

For the clinical diagnosis, in addition to the classical triad, three characteristic signs are described: the Love pin test, the Hildreth test and the cold immersion test.⁹ The Love pin test involves the application of targeted pressure with a clip or the head of a pin, and the area of pain defines the topography of the tumor.

The Hildreth test is performed by inducing transient ischemia using a tourniquet, and is considered positive when the patient manifests pain relief with the provocation of ischemia, and sudden severe pain when the tourniquet is released. The cold immersion test is positive when the hand is immersed in cold water and this causes severe pain in and around the injury. This is produced by stimulation of the receptors that are sensitive to cold, producing a vasodilation of the arteriovenous canals, which dilate in response to the cold to avoid excessive heat loss. Bhaskaranand and Navadgi,⁴¹ in a study with 18 patients, reported a sensitivity of 100% and a specificity of 78% in the Love test, and 100% of sensitivity and specificity in the cold immersion test, while the Hildreth test was 71.4% sensitive and 100% specific.⁴¹ Although these tests are characteristic, we found 19 publications that do not specify their complete results.^{1,4,8,9,12,13,16,18,19,22,23,27,28,30,33–36,40}

In the literature, the diagnosis is described with an average delay of seven years since the onset of symptoms, which may be due to the lack of knowledge of the clinician regarding this pathology. Its nonspecific clinical presentation can raise the diagnostic doubt with differentials such as neuroomas, foreign bodies, melanoma, pigmented nevi, hemangiomas and hyperplasia of the Pacinian corpuscle.^{20,35}

They are generally small lesions of less than 10 mm, which, at the beginning, may not be palpable due to their size and depth. In these cases, for the diagnosis, there are complementary clinical tests such as transillumination, which is only mentioned by Bousbaa and Amhaji.²⁹

In the present review, the average age at presentation was of 47 years, which coincides with previous reviews on the subject,³ in which the mean age shows a peak in the fifth decade of life for men, and in the fourth for women.

These tumors are more frequent in the distal segment of the fingers, given the higher density of the glomus bodies in that area.¹ In total, 70% of the articles report glomus tumors at the subungual level, followed in 20% of cases of exclusive presentation at the level of the fingertip, and 10% at the digital level, in the first, second or third phalanges.

It occurred more frequently at the level of the index finger (30%), followed by the thumb, ring, and little fingers, the latter with the same proportion each (19%); this differs from previous reviews, in which the thumb was the most affected and the little finger, the least affected.³

According to their clinical presentation, these tumors are classified as solitary or multiple, the former being the most frequent. In our initial search, we found publications on multiple extradigital tumors; not so on multiple digital tumors.

We found no evidence of the indication for imaging tests, although plain radiography was the most requested test in the present review. Radiography enables the assessment of the presence of bone erosion, found in most subungual tumors.³⁵ Ultrasound and MRI are reserved for doubtful cases, in which the symptoms do not present the classic triad, and cases of recurrent tumors, or of multiple or atypical locations.³⁶ On the MRI, they are described as mildly hypointense to mildly hyperintense on T1-weighted images and hyperintense on T2-weighted images. Studies^{12,40} show that the MRI is highly sensitive years after the onset of symptoms, detecting 82% to 90% of glomus tumors in the hand. However, a small tumor cannot be ruled out with a negative MRI result; therefore, when there is clinical suspicion, surgery is recommended.^{11,37}

The treatment of choice is complete surgical excision. In subungual tumors, this can be performed through a transungual approach, which requires careful extraction of the nail plate and a longitudinal incision in the bed. This approach is the most widely used method, enabling complete removal of the tumor and resulting in a lower recurrence rate.⁴ (► **Figure 2**).

In proximal subungual lesions, a lateral subperiosteal approach has been described. The main disadvantage is the lower visibility and the consequent risk of incomplete tumor excision.³²

Recurrence rates vary depending on the technique used and on the incomplete excision of the tumor. It has been observed that symptoms that appear days to weeks after the surgical excision may be due to incomplete excision, whereas, when symptoms appear 2 to 3 years after surgery, this may indicate multiple tumors.³⁷

Fig. 2 Clinical case of glomus tumor. (A) The tumor is seen after resection of the nail plate. (B and C) With the dissecting forceps, the eponychium flap is indicated below which the matrix defect is closed. (D) Repositioning of the nail plate.

Kim et al.³⁹ analyzed the risk factors related to recurrence and complications in the postoperative period. The factors analyzed related to a higher risk of recurrence were tumor size, bone erosion, anatomical location, surgical approach, and the method used. Recurrence did not present a greater statistical significance in the risk groups analyzed. The complications described were nail deformities, generally minor striations, and numbness of the fingertips, with no statistically significant differences regarding the approach used. The transungual approach is thought to offer a better view of the surgical field for tumor excision, but it has the disadvantage of damaging the nail bed, thus presenting a higher incidence of postoperative nail deformity. A nail-sparing approach prevents adhesion between the matrix and the eponychium during healing of the nail bed, avoiding postoperative nail deformities.

In the present review, minor complications, such as nail deformity,^{1,28} and, less frequently, hypoesthesia and hypertrophic scar, have been found.³³

Glomus tumors are classified into three types according to their composition: glomangiomas or ganglioma are formed mainly by vessels (60%); solid glomus tumors are mainly composed of glomus cells (25%); and glomangiomyoma shows a predominance of smooth-muscle cells (15%).^{10,32} In the present review, the histological type^{15,23} is only reported in two cases.

There are limited reports of glomangiosarcoma, a malignant variant of glomus tumor described in less than 1% of the cases, more frequently at visceral level; the established guiding criteria for malignancy are size greater than 2 cm, deep location, and presence of atypical mitoses or nuclear atypia.¹¹ We did not find articles that report the presence of glomangiosarcoma, a malignant variant of glomus tumor.

Glomus tumors that show nuclear pleomorphism without any other malignant feature have been defined as symplastic glomus tumors, which behave clinically as benign, and must be differentiated from glomangiosarcoma. This atypia is recognized as a degenerative change, and is accepted as benign.^{15,23}

Since glomus tumor is a rare pathology, case reports or cohort studies carried out with methodological rigor are important, including as much detail as possible regarding the findings, once this enables the development of a database to improve diagnostic and therapeutic procedures.

Conclusions

Glomus tumors are a mostly benign neoplasm, with no reported cases of malignancy found in the present review. Although most studies report spontaneous pain and the classic clinical triad, its presentation is nonspecific. It is a rare pathology, which coincides with the fact that in the last 10 years almost all of the publications found are case reports. These factors together contribute to the late diagnosis: in the present review, 1 to 10 years elapsed since the onset of symptoms. Plain radiology was the most requested test in the present review, followed by ultrasound and MRI, and its main indication is to rule out differential diagnoses in cases of diagnostic doubt.

In rare pathologies like this, the publication of case reports and series, as well as reviews, is important in order to generate scientific evidence that contributes to decision-making at a practical level.
