Abstract

Epidermoid cyst is a congenital benign lesion, rarely seen in the topography of the fourth ventricle. The authors report a case of a 48-year-old patient with headache and cerebellar ataxia due to an epidermoid cyst in the fourth ventricle. We performed a surgical resection with histopathological confirmation of the lesion.

Resumo

O cisto epidermoide é uma lesão congênita e benigna, sendo raro em topografia do quarto ventrículo. Os autores relatam um caso de uma paciente de 48 anos, com quadro clínico de cefaleia e ataxia cerebelar decorrentes de um cisto epidermoide localizado no quarto ventrículo. Foi realizada uma ressecção cirúrgica com confirmação anatomopatológica da lesão.

Introduction

Epidermoid cysts are benign, congenital, and rare lesions corresponding to approximately to 0.2% to 1.8% of all intracranial tumors.¹ Because of its pearly appearance, in 1829, Cruveilhier described these tumors as *Tumeur Perlée*. Virchow and Bailey coined the term “Pearl Tumor”; and, in 1836, Müller introduced the “Cholesteatoma” denomination.² Approximately 5% of epidermoid cysts affects the fourth ventricle, which is one of the less common locations.³ According to Sengupta and Singh, in 2015, only ~100 cases of epidermoid cyst in the fourth ventricle had been reported.⁴ The aim of this study is to describe the clinical characteristics

of an epidermoid cyst located in the fourth ventricle and the chosen therapy, as well as provide a brief review of literature.

Case Report

This study reports on a 48-year-old woman, referring frontal occipital and pulsating headache about six months before admission. She was non-reactive to the use of analgesics, associated with nausea, dizziness, and vomiting. After two months, she developed gait disturbance, when she was diagnosed with “brain tumor,” and underwent operation for placement of ventriculoperitoneal (VP) shunt. The patient was referred for this service for elective surgery for resection

of the tumor. The initial examination showed bilateral nystagmus and ataxic gait.

Magnetic resonance showed a mass lesion in the fourth ventricle, with Lushka foramen invasion, and spread to the magna cistern. It showed a hypointense appearance on T1 sequence and hyperintensity on T2 without enhancement after contrast injection. There was heterogeneity in FLAIR sequence and hyperintensity on the diffusion image (► **Fig. 1**).

During surgery, the patient was positioned in the prone position. We performed median occipital craniotomy. We achieved a gross total resection of the lesion, which had a pearly appearance (► **Figs. 2 and 3**). The histopathological study showed capsular tissue rich in keratin and protein, and predominantly cystic content, findings consistent with epidermoid cyst (► **Fig. 4**).

In the immediate postoperative period, there were no complications and the patient developed clinically well during follow-up of six months.

Discussion

The epidermoid cysts are benign, congenital, and rare, corresponding to roughly 0.2% to 1.8% of all intracranial tu-

mors.¹ Five percent of these occur in the fourth ventricle, which is the least common location, with only ~100 cases described in the literature.^{3,4}

Epidermoid tumors likely originate from the retention of ectodermal cells in the central nervous system because of defects of the neural tube between the third and fifth week of pregnancy.⁵

These tumors can occur anywhere in the intracranial cavity, but the majority is in intradural and paramedian position, especially in the pontine angle (40–50%); or parasellar region (30%).¹ The involvement of the fourth ventricle is the least common.⁴

These tumors are typically asymptomatic until the fourth to fifth decade of life, presenting the average age of 40 years. Initial symptoms found in tumors affecting the fourth ventricle can include headache, dizziness, gait disturbances.⁶ Diplopia, dysphagia, and hoarseness may appear in later stages, when there is involvement of the cranial nerves.^{3,7} In this case, we present a 48-year-old patient whose initial symptoms were headache, nausea, vomiting, and gait ataxia, in agreement with those found in the literature.

The diagnosis of these tumors is given by the correlation between symptoms and radiographic findings. In Magnetic Resonance Imaging (MRI) on T1 sequence, they typically appear as a hypointense mass, and hyperintense on T2, and diffusion sequences. Differential diagnoses include arachnoid cysts, dermoid cysts, hydatid cyst, and neurocysticercosis.^{1,8}

The standard treatment for epidermoid tumors is gross total surgical resection.¹ In certain situations, these tumors can be adjacent to quite delicate neurovascular structures, such as the floor of the fourth ventricle. In these cases, because of the high risk of neurological morbidity, total resection must be replaced by a subtotal approach.³ In the case of tumors located in the fourth ventricle, the approach of choice is to perform a median sub occipital craniotomy.^{9,10} The surgical excision is based on the intracapsular debulking and extracapsular dissection.¹¹

However, two complications may alter the course of the disease: aseptic meningitis and malignant transformation.⁹ Aseptic meningitis is the main influencing factor of

postoperative course.¹² It does not occur only when performing partial excision of the lesion, as classically described.⁹ For aseptic meningitis to occur, a single contact of the cystic contents of the tumor with the cerebrospinal fluid during surgery is enough.¹³ Treatment of aseptic meningitis is through repeated lumbar punctures and corticosteroids.⁹ On the other hand, malignant transformation is an extremely rare complication and, when present, is associated with the development of squamous cell carcinoma.^{14,15}

In the case of incomplete tumor resection, although the growth rate of residual lesion is as slow as the original tumor, it is necessary to follow-up with annual magnetic resonance.¹⁶ In such cases, studies indicate recurrence of the tumor at an interval equal to the patient's age at diagnosis plus nine.⁴

The surgical approach must be carefully performed, and based on a combination of symptoms and radiological data, considering the slow rate of residual tumor growth.¹¹

The literature indicates that adjuvant therapy for epidermoid cysts is scarce and, according to some authors, nonexistent.¹⁷ However, Parikh et al reported a case of success in inhibiting recurrence of a benign intracranial epidermoid cyst with the use of radiation during two years of follow-up.¹⁸

Conclusion

Epidermoid cysts of the fourth ventricle are rare and benign intracranial lesions. They tend to acquire large sizes before manifesting symptoms or cerebellar dysfunction. Early symptoms result from increased intracranial pressure, which can be minimized by placing a ventriculoperitoneal shunt. MRI is of great diagnostic value, and total surgical excision should be considered the procedure of choice. However, due to slow growth, in the case of adherence to very delicate structures of the nervous system, a subtotal approach must be considered and is associated with satisfactory results.

Conflict of Interest

The authors declare that they have no conflict of interest.
