Abstract

Objective To evaluate the postoperative functional and radiographic outcomes of the shoulder of patients submitted to transosseous suturing of a greater tuberosity fracture (GTF) through an anterolateral route and the influence of the glenohumeral dislocation on these outcomes.

Methods We conducted a retrospective study and functional assessment using the Constant-Murley score. The distance between the greater tuberosity and the joint surface of the proximal humerus (in true anteroposterior radiographs) after the union was calculated. We used the Fisher exact test for the categorical independent variables, and the Student *t* or Mann-Whitney test for the non-categorical variables.

Results In total, 26 patients met the inclusion criteria, and 38% of the sample presented an association between glenohumeral dislocation and GTF. The mean Constant-Murley score was of 82.5 ± 8.02 points. The presence of an associated dislocation did not alter the functional outcome. The mean distance between the

greater tuberosity of the humerus and the joint surface of the humeral head after the union was of $9 + 4.3$ mm below the articular line of the humeral head. The dislocation led to a lower level of reduction, but this did not influence the Constant-Murley score. **Conclusion** The cases of GTF submitted to surgical treatment with transosseous sutures had good functional outcomes. The presence of dislocation made the anatomical reduction of the greater tuberosity difficult. However, it did not influence the Constant-Murley score.

Resumo

Objetivo Avaliar os resultados funcional e radiográfico pós-operatórios do ombro, em pacientes submetidos a sutura transóssea de fratura da tuberosidade maior (FTM) por acesso anterolateral, e a influência da luxação glenoumeral nesses resultados.

Materiais e Métodos Realizou-se estudo retrospectivo e avaliação funcional (pela escala de Constant-Murley). Calculou-se a distância entre a tuberosidade maior e a superfície articular do úmero proximal (por meio de radiografia em incidência anteroposterior verdadeira) após a consolidação. Usou-se o teste Exato de Fisher para as variáveis independentes categóricas, e os testes *t* de Student ou de Mann-Whitney para as não categóricas.

Resultados Ao todo, 26 pacientes preencheram os critérios de inclusão. A associação de luxação glenoumeral com FTM foi observada em 38% da amostra. A média da pontuação na escala de Constant-Murley foi de $82,5 + 8,02$. A presença de luxação associada não alterou o resultado funcional. A distância média da consolidação da tuberosidade maior do úmero em relação à superfície articular da cabeça umeral foi de $9 + 4,3$ mm abaixo da linha articular da cabeça umeral. Pacientes com luxação associada evoluíram com redução menor, mas isso não influenciou na pontuação na escala de Constant-Murley.

Conclusão As FTMs submetidas ao tratamento cirúrgico com sutura transóssea evoluíram com bom resultado funcional. A presença de luxação dificultou a redução anatômica da tuberosidade maior. Entretanto, isso não influenciou na pontuação na escala de Constant-Murley.

Introduction

Greater tuberosity fractures (GTFs) account for 20% of fractures of the proximal humerus.¹ Although their prevalence is low, GTFs are functionally relevant because they affect the attachment site for the supraspinatus and infraspinatus muscles, playing a role in shoulder joint flexion, abduction, and external rotation. Thus, the anatomical reduction of the greater tuberosity is fundamental for a good functional outcome for the shoulder.² Approximately 10% to 30% of dislocations are concurrent with GTF³ and a potential Hill-Sachs lesion.⁴ Reduction of the glenohumeral dislocation can lead to concomitant reduction of the greater tuberosity. One study⁵ showed that only 4% of patients with GTF and anterior dislocation of the humerus required surgical treatment to correct the fracture deviation.

The greater tuberosity requires surgical treatment if the fracture deviation is ≥ 5 mm.⁶ Surgery is more indicated for young patients or those performing activities with arm elevation above the head.⁷ The surgical treatment aims at an anatomical reduction between the greater tuberosity and

the humeral head in a portion approximately 9 mm distal to its most proximal aspect.⁷ An improper reduction may cause secondary impingement syndrome and/or cuff failure (high tuberosity), or tendon rupture due to excessive stress (low tuberosity).⁶

The deltopectoral and anterolateral approaches are the most used to treat proximal humerus fractures.⁸ The anterolateral approach is lateral to the proximal humerus, and it provides better exposure of the greater tuberosity.⁹

Fracture morphology may influence the osteosynthesis technique. The treatment of a large-fragment GTF (split type) uses a plate and a screw compression system. A tension band or transosseous suture is an option for the fixation of comminuted and small fragments.⁷

Few studies have evaluated the surgical treatment of GTFs and the influence of a glenohumeral dislocation on the postoperative functional outcome of the shoulder.

Our primary objective was to evaluate shoulder function and the final position of GTF union after a transosseous suture by the anterolateral approach. A secondary goal was

to assess whether an associated glenohumeral dislocation could influence these outcomes.

Materials and Methods

We conducted a retrospective study analyzing medical records from patients undergoing osteosynthesis of the greater tuberosity with bone sutures from January 2010 to August 2019.

The inclusion criteria were the following: patients over 18 years old with GTF (deviation greater than 5 mm) surgically treated with transosseous suture via the anterolateral approach, and a minimum follow-up of one year postoperatively.

The exclusion criteria were the following: patients with proximal humerus fractures classified as Neer III and IV (such as, lesser tuberosity fractures and surgical or anatomical neck fractures associated with a GTF)¹⁰ or previous shoulder injuries (cuff or neurological lesions).

The patients were placed in the beach chair position. The anterolateral¹¹ (Mackenzie) approach was used in every case. We performed an incision of approximately 5 cm inferiorly to the anterior extremity of the acromion, running along the lateral region of the arm. Then, we divided the deltoid muscle, in the same direction as its fibers, between the anterior and middle portions. We did not isolate the axillary nerve if a 5-cm incision was enough for osteosynthesis. However, if wider exposure were required, the nerve was dissected and protected with a Penrose drain. Next, we perforated the greater tuberosity bone (in cases with a larger bone fragment) or sutured the supraspinatus or infraspinatus tendons. Then, we perforated the humeral diaphysis and performed the transosseous suture with non-absorbable #5 Ethibond (Ethicon, Inc., Bridgewater, NJ, United States) suture.

We reviewed the demographic and trauma data from the medical records. The postoperative functional assessment used the Constant-Murley Shoulder Outcome Score.¹² The preoperative evaluation of the axillary nerve used the corresponding dermatome sensitivity test. Postoperatively, we investigated dermatome changes and the presence of inferior humeral subluxation on the clinical or radiographic examinations.

The preoperative and postoperative radiographic analyses were based on the true anteroposterior view, lateral view of the scapula, and axillary view. The final position of fracture healing corresponded to the distance (in millimeters) from the apex of the greater tuberosity to the joint surface of the proximal humerus (true anteroposterior view) (► **Figure 1**). Consolidation was complete when there was no fracture line in at least two views. The Radiographs and measurements were performed using the Synapse (Fujifilm Healthcare, Lexington, MA, United States) digital radiology software.

The inferential analysis used the Chi-squared or Fisher exact tests for the independent categorical variables (comorbidities, gender, fracture side). The numerical variables were analyzed after normality evaluation by the Kolmogorov-

Fig. 1 Distance (mm) between the greater tuberosity fracture and the humeral joint surface.

Smirnov test using the Student *t* (age) or the Mann-Whitney (distance to the final position of fracture union) tests. Data analysis was performed using the Statistical Package for the Social Sciences (IBM SPSS Statistics for Windows, IBM Corp., Armonk, NY, United States) software, version 27.0, assuming a significance level of 5%.

The institutional ethics committee approved the study under CAEE number 73273317.8.0000.5404.

Results

The present study evaluated 59 patients, and 33 subjects were excluded for not meeting the inclusion criteria; therefore, the final sample consisted of 26 patients. The main reasons for exclusion were the presence of a fracture line extending to the lesser tuberosity and loss to follow-up. The mean follow-up time was of 15 + 13 months.

The mean age of the study participants was of 39.72 + 16.27 years. Most subjects were male, and the right side was most affected (73%). The main comorbidities were diabetes mellitus, drug addiction, alcoholism, smoking, epilepsy, and hypothyroidism. Among them, epilepsy was the most prevalent (11%). ► **Table 1** summarizes the demographic data.

In total, 10 patients (38%) presented a glenohumeral dislocation associated with GTF. Men presented more dislocations than women ($p = 0.05$).

The average Constant-Murley score was good (82.5 + 8.02 points). The presence of an associated dislocation did not alter the functional outcome (► **Table 2**).

Radiologically, the average time until consolidation was of 2.2 + 0.9 months. The final position of the greater tuberosity apex was 9 + 4.3 mm below the joint surface of the humeral head. There were no cases of postoperative reduction above

the level of the humeral head. The final position of the GTF did not influence the functional assessment ($p = 0.32$).

Patients with dislocations presented lower levels of greater tuberosity reduction (hyperreduction) compared to those with no dislocation ($p = 0.01$). However, the presence of dislocation did not influence the Constant-Murley score (→ **Table 2**).

Two patients presented greater tuberosity resorption. There were no cases of postoperative infection or axillary nerve injury. A single case required dissection and protection of the axillary nerve because fracture reduction needed an incision larger than 5 cm.

Discussion

In a study with 610 proximal humerus fractures to perform an epidemiological comparison of GTFs (group I) with other types of proximal humerus fractures (group II), Kim et al.¹³ concluded that younger patients (with mean age of 42.8 years) and men (67.8%) were predominant in group I, which is consistent with our findings. In contrast, other types of proximal humerus fracture predominated in older subjects and women.¹³ This same study¹³ reported a glenohumeral dislocation rate of 6.9% in group I and of 3.4% in group II. Robinson et al.¹⁴ analyzed 2,208 traumatic anterior disloca-

tions and observed a 34% incidence of associated GTF, which also consistent with our rate of 38%.

We did not observe a relationship between comorbidities, age, fracture side, and the prevalence of GTF-associated dislocation (→ **Table 1**). The prevalence of comorbidities is higher in older patients. In addition, they tend to present fractures involving other anatomical structures (such as the surgical neck, the lesser tuberosity) than isolated GTFs.^{13,15}

The average Constant-Murley score was good, and its lowest value was of 72 points. Rouleau et al.¹⁶ observed a good or excellent outcome in 80% to 100% of their patients. Flatow et al.¹⁷ found good functional outcomes and fracture healing in their case series.

We did not observe axillary nerve-related complications. Theoretically, the axillary nerve is more at risk in the anterolateral approach (incisions larger than 5 cm) compared to the deltopectoral approach. However, some authors^{18,19} have shown that the anterolateral approach is safe for the axillary nerve, resulting in good functional outcomes. Similarly, a systematic review²⁰ of 24 articles involving 831 patients submitted to the anterolateral approach found a low incidence of iatrogenic axillary nerve injury and a good functional outcome (Constant-Murley score of 75.2) after osteosynthesis of a proximal humerus fracture.

The presence of a dislocation influenced the quality of the postoperative reduction ($p=0.01$) in the present study (► **Table 2**). In patients with a dislocation, the median distance from the apex of the greater tuberosity to the joint surface was greater (9.98 mm) than in subjects without dislocation (6.92 mm). One hypothesis for this difference is the presence of a Hill-Sachs lesion, which could alter the anatomical parameters and make it difficult to reduce the greater tuberosity.

Bhatia et al.²¹ studied GTFs with displaced and comminuted fragments treated with open reduction and anchor fixation. These authors²¹ observed fragment consolidation below the joint level of the humeral head in most patients. The study did not specifically assess fracture comminution. However, we believe that the presence of a Hill-Sachs lesion acts in the same way, as it changes the anatomical parameters and makes fracture reduction difficult.

Regarding our results, the presence of glenohumeral dislocation did not influence the functional assessment of the shoulder through the total Constant-Murley score. Several aspects of the score (such as lateral rotation and strength) were not statistically different in patients with or without GTF-associated dislocation. Moreover, the final position of the greater tuberosity after surgery did not influence the Constant-Murley score. We hypothesized that tuberosity reduction below the humeral joint surface resulted in no secondary subacromial impingement or functional deterioration. Hébert-Davies et al.²² observed a mean Constant-Murley score of 83 points in a sample of patients with GTF, which is very similar to our findings (84 points).

The present study has some weaknesses. Its main limitation is the retrospective design. In addition, the reduced number of patients and the 1-year follow-up may decrease the rate of identification of complications. However, the lower prevalence of GTFs, especially those treated surgically, favors the performance of cross-sectional or retrospective studies to create subsidies for further prospective investigations.

Conclusion

The cases of GTF submitted to surgical treatment with transosseous sutures through the anterolateral approach had good functional outcomes.

A glenohumeral dislocation made the anatomical reduction of the greater tuberosity difficult. However, it did not influence the functional outcomes of the patients' shoulders.

Financial Support

The authors declare that the present study did not receive financial support from public, commercial, or non-profit sources.

Conflict of Interests

The authors have no conflict of interests to declare.
