Keywords

Perforating veins, varikosis, duplex ultrasound, venous insufficiency

Summary

Perforating veins connect the superficial and deep venous system. In the diagnosis and treatment of varicosis, perforating veins are of high importance in search for the most proximal and most distal point of insufficiency. The examination of the perforating veins is a challenge in duplex sonography. The pathophysiological relevant significant incompetent perforating veins should be treated with surgical or minimal invasive methods.

Schlüsselwörter

Perforansvenen, Varikosis, Duplex, Veneninsuffizienz

Zusammenfassung

Perforansvenen verbinden die epifaszialen Beinvenen mit den subfaszial gelegenen tiefen Venen und dienen zur Drainage des venösen Blutflusses. In der Diagnostik und Therapie einer Varikosis haben die Perforansvenen eine große Bedeutung beim Aufsuchen des proximalen und distalen Insuffizienzpunkts. Die Untersuchung der Perforansvenen ist eine Herausforderung in der Duplexsonographie. Die pathophysiologisch bedeutsamen insuffizienten Perforansvenen sollten operativ oder minimal invasiv ausgeschaltet werden.

Definition

A perforating vein is one that connects a vein that is part of the deep truncal vein system with an epifascial vein that penetrates the fascia. The physiological direction of flow of a perforating vein is from the surface into the deep tissues. If a perforating vein is incompetent, then the direction of flow in it is reversed and the superficial vein becomes congested (1) (► Fig. 1).

More than 40 perforating veins that are always present in a particular location have been described in the literature (2). Perforating veins are considerably more numerous in the lower leg than in the thigh.

The perforating veins most commonly involved in varicose veins are depicted in ► Figures 2 and 3.

Classification

In routine clinical practice, perforating veins are often known by the names of the physicians who first described them. However, according to the more recent, international nomenclature, the perforators are no longer described eponymously, but on the basis of their topography. However, the old designations are still widely used in clinical parlance (3). For example, according to the new nomenclature, Cockett's perforators are now called the posterior tibial perforator veins (► Figs. 5 and 6). A summary of the old and new names is shown in ► Table 1.

Diagnosis

Clinical and imaging methods can be used to assess the functioning of perforator veins during the diagnostic workup of varicose veins and CVI.

Fig. 5 Recurrent varicosis after high ligation and stripping of the right GSV, with Cockett II perforator incompetence

Clinical diagnosis

Perforator vein incompetence usually leads to pathologically dilated fascial gaps that are often painful on palpation. Incompetent perforators are generally detectable even on simple inspection of the erect patient by the blow-out phenomenon.

Venous function tests (Perthes, Mahorner-Ochsner, Trendelenburg and Pratt tests) can be used for further clinical diagnosis

Colour-coded duplex ultrasonography

The simplest way to demonstrate perforator incompetence is by duplex ultrasonography. The dilated perforator veins are readily visible in the B-mode image (► Fig. 7).

Only perforators that are pathologically dilated are generally detectable by ultrasound. In most of them, the blood flows from the surface into the deep tissues, as drainage for the reflux in the truncal vein or in the tributaries to the deep leg veins. With retrograde flow, a perforator vein is the source of reflux for a varicose vein (4).

Perforators can also be readily visualised in colour-coded duplex ultrasonography. The physiological flow of blood in a perforator is directed from the surface into the deep tissues. Blood flow in a perforator can be shown under the Valsalva provocation manoeuvre or on manual compression of the calf. This increases pressure in the deep veins and the blood is directed proximally and into the perforating veins. If, due to reflux or volume overload, a perforator is dilated, an outward-directed flow is present during muscular systole (4) (► Figs. 8 and 9).

The flow after decompression is relevant for diagnosis. If flow towards the surface is present during diastole, then the perforator is incompetent.

The provocation tests should be carried out using Valsalva's pressing manoeuvre, by movement of the toes (Wunstorf manoeuvre) or by manual calf compression. A tourniquet applied proximal to the perforator can lead to false pathological results in the manoeuvre, because the incompetent

vein is closed proximally by the tourniquet and the recirculation in diastole, that is otherwise present, is prevented. After decompression, blood flow from the deep vein drains into the distal incompetent superficial segment via the dilated perforator. Thus a vein that, under physiological conditions without a tourniquet, serves re-entry appears incompetent.

The more distal a perforating vein lies in the leg, the more unlikely it is to serve recirculation as an incompetence point. The exceptions are the secondary varices after trauma to the calf. Single refluxing muscle veins are more often present after trauma. These then fill side branch varices and form their proximal point of incompetence. (4)

Fig. 8
Pretibial perforating vein with no pathological reflux

Fig. 9
Incompetent perforating vein, flow after decompression is directed to the surface

The incompetent muscle veins are frequently the origin of subcutaneous reticular varices. They are generally post-traumatic varices.

It is very rare that a dilated perforating vein also fills an already refluxing vein, but this can occur with a secondary varicose vein. If the vein above the perforator is already refluxing, the flow patterns in the saphenous vein and perforating vein must be accurately compared before the latter is designated as an incompetent perforator needing treatment. Its flow pattern must be predominantly directed outwards and the flow patterns of the distal vein lead to a larger reflux volume than in its proximal portion. This investigation is only possible in the PW mode.

The perforating veins can serve as drainage. Most often they are veins in the calf, especially the Cockett group and the paratibial perforators (► Fig. 10).

Phlebography

Phlebography with contrast agent – previously often used in the diagnosis of perforator incompetence – has become less important in view of the possibilities of duplex ultrasound. The indication for phlebographic diagnosis is to be made in the case of a questionable result following duplex ultrasound examination. It can be worthwhile in rare cases with legs that have undergone several operations, after recent thrombosis or in extreme obesity (► Figs. 11 and 12).

Venous leg ulcer

There is a correlation between the number of incompetent perforators and the severity of CVI and/or the development of a venous leg ulcer. Perforator incompetence is rarely the sole cause of the venous ulcer, but the

Fig. 10 Incompetence of the great saphenous vein with conjugating side branch varicosities, drainage via the perforating vein (arrows show direction of flow).

Cockett perforators are more commonly involved. Phlebodynamometric studies indicate that the risk of developing a venous ulcer increases with the severity of haemodynamic decompensation. Permanent healing of an ulcer is only likely with a far-reaching normalisation of the ambulatory venous hypertension. If incompetence is confined to the superficial venous system and accompanying perforator incompetence, then eradication of the epifascial reflux components is usually sufficient. In contrast, if there is irreversible damage of the deep venous system at the same time, the venous hypertension will persist after treatment of the epifascial incompetence, even after additional eradication of incompetent perforators (5, 6).

A few studies show that after abolition of epifascial reflux (high ligation and stripping), the number of preoperative incompetent perforating veins decreases (7, 8) (► Figs. 13 and 14).

Treatment methods

Eradication of the incompetent perforating veins should be considered if the incompetence is of clinical and/or haemodynamic relevance (9–11). The benefits of a routine ablation of perforators in uncomplicated, purely epifascial varicosis are not proven

(11–13). Provided the skin condition is healthy, surgical ligation of the perforating veins is currently the technique with the fewest complications (11) (► Figs. 15 and 16).

Exposure of the perforating vein according to Linton (16), without consideration of its pathophysiological importance and the skin condition, is no longer recommended (11).

Cases of endovenous treatment of perforator incompetence have been described in the literature (17, 18). However, there is still no treatment recommendation for endovenous laser or radiofrequency treatment of perforators (11).

Endoscopic perforator
ligature (schematic
representation)

Duplex-guided foam sclerotherapy of perforators has shown good results in studies and should be preferred as a possible treatment if the skin condition is poor (19, 20).

Conclusion

Perforating veins are a feature of the lower extremity and present a challenge in the diagnosis and treatment of chronic venous insufficiency. The pathophysiological significance of a perforating vein can be investigated by careful duplex diagnosis. The perforating veins can form a point of incompetence, but more often serve as drainage for venous recirculation.

Conflict of interest

The authors declare that there are no conflicts of interest.

Ethical guidelines

No studies in humans or animals were conducted for the manuscript.
