

Attention deficit hyperactivity disorder and drug addiction rehabilitation patients

Transtorno de Déficit de Atenção e Hiperatividade e pacientes em reabilitação de drogadição

Carlos Henrique Ferreira Camargo¹, Tarcísio Fanha Dornelles¹, Karin Barszcz¹, Eduardo Antunes Martins¹

ABSTRACT

Objective: Attention deficit hyperactivity disorder (ADHD) is characterized by a persistent pattern of inattention or hyperactivity. This study aimed to investigate the relationship between ADHD and drug dependence. **Methods:** The presence and severity of ADHD and substance use were evaluated through questionnaires in 80 adult patients in therapeutic communities. **Results:** No difference in drug use or dependence prevalence between ADHD and non-ADHD patients was found. However, ADHD patients had lower ages on admission ($p = 0.004$) and at first contact with cocaine ($p = 0.033$). In ADHD patients, there was a negative correlation between the age at first use of cannabis and the subsequent severity of cannabis use ($p = 0.017$) and cocaine use ($p = 0.033$). **Conclusions:** Though there was no difference in prevalence of drug use among groups, results show that ADHD in patients in therapeutic communities may cause different addiction patterns, such as earlier use of cocaine and admission, and a more severe use of cocaine correlated to earlier contact with cannabis.

Keywords: attention deficit disorder with hyperactivity; substance-related disorders; cocaine.

RESUMO

Objetivo: O Transtorno de Déficit de Atenção e Hiperatividade (TDAH) é caracterizado por um padrão de desatenção ou hiperatividade. Este estudo investigou relações entre TDAH e dependência de substância. **Métodos:** Prevalência e gravidade de TDAH e de uso de substância foram avaliadas em oitenta pacientes adultos de comunidades terapêuticas. **Resultados:** Não houve diferença de prevalência de uso e dependência de substância entre pacientes com e sem TDAH. Pacientes TDAH tiveram menor idade de admissão ($p = 0,004$) e de primeiro contato com cocaína ($p = 0,033$). Em pacientes TDAH, houve correlação negativa entre idade de primeiro uso de *cannabis* e gravidade do uso de *cannabis* ($p = 0,017$) e cocaína ($p = 0,033$). **Conclusões:** Mesmo sem haver diferença na prevalência de uso de substância entre os grupos, conclui-se que o TDAH nos pacientes de comunidade terapêutica pode ter induzido padrão diferente da drogadição, como idade precoce de admissão e de uso de cocaína, e uso mais grave de cocaína relacionado a contato precoce com *cannabis*.

Palavras-chave: transtorno do deficit de atenção com hiperatividade; transtornos relacionados ao uso de substâncias; cocaína.

Attention deficit hyperactivity disorder (ADHD) manifests as a behavioral pattern that leads to significant social, educational and occupational impairment. The main characteristics of the disorder are inattention, hyperactivity and impulsivity¹. The diagnosis of ADHD is clinical and is based on a persistent, early-onset clinical picture that manifests in different settings and leads to functional loss².

A failure in behavioral inhibition is believed to lead to the predominant symptoms of ADHD: hyperactivity, inattention, distraction and impulsivity³.

The changes in the catecholaminergic pathways are believed also to involve the nucleus accumbens, with impairment of selective attention and the reward system⁴, which may be associated with a greater risk of substance use and dependence⁵. The risk

of dependence on alcohol or other substances is significantly higher in adolescents with attention-related difficulties than in healthy adolescents⁶. Hence, because of the impulsivity and inattention associated with the condition, ADHD may be a risk factor for substance use disorder⁵, a set of cognitive, behavioral and physiological symptoms that cause occupational impairment as a result of the use of a particular substance. Substance dependence is a clinical condition at the more severe end of the substance use disorder spectrum. Even when occupationally incapacitated, dependent individuals continue to use substances. Drugs described as potentially causing dependence include nicotine, alcohol, cannabis, and cocaine and its derivatives¹.

The aims of this study were to identify the presence of ADHD and its subtypes in patients in rehabilitation for chemical

dependence and compare the patterns of drug-addiction, with regard to frequency and severity of substance use and dependence, age on admission and age of first use, between ADHD and non-ADHD patients. In addition, the study aimed to investigate the correlation of ages at first use of substance, age on admission to the therapeutic community and severity of use of substance, in order to explore the relationship between ADHD symptom frequency and the pattern of substance use.

METHODS

Eighty consecutive patients (53 males and 27 females) admitted between July 2013 and December 2014 to two rehabilitation centers for chemical dependents (*Rosa Mística* and *Padre Wilton* therapeutic communities) were selected. Inclusion criteria were: having a history of drug use; being in a rehabilitation center; and being aged 18 or over. Exclusion criteria were: refusing to sign the voluntary informed-consent form and cognitive and behavioral incapacitation.

The study was approved by the human research ethics committee at Ponta Grossa State University under reference no. 261.273.

Definitions and criteria

The diagnostic criteria in the Diagnostic and Statistical Manual of Mental Disorders (DSM-IV-TR)⁷ were used to identify the presence of ADHD and to classify it into subtypes. Individuals were considered to be substance users if they reported having had at least one contact with the substance during their lives.

The Adult ADHD Self-report Scale symptom checklist (ASRS-18) was applied to qualify and quantify ADHD^{8,9}, mainly by accessing the frequency of ADHD symptoms. In the evaluation, the patients were questioned about symptoms present during primary school attendance, and therefore without influence of possible negative outcomes of drug use disorder that could simulate symptoms of inattention and hyperactivity.

The Alcohol, Smoking and Substance Involvement Screening Test (ASSIST) was used to identify, qualify and quantify substance use and dependence^{10,11}. The test was applied to investigate alcohol, tobacco and cannabis use, as well as the use of cocaine and its derivatives. The total score in this test was given by the sum of the values assigned to the ASSIST questions related to occupational impairment caused by substance use or dependence. Substance use was considered to be present if an individual had had contact with substances at least once in their life, and dependence was defined as corresponding to a score of more than 16/20.

Assessment of ADHD symptoms, substance use and dependence

The voluntary informed-consent form was explained to patients. After it had been signed, the ASRS-18 and ASSIST questionnaires were applied, in that order.

During the first part of the ASSIST questionnaire, patients were asked what age they were when they first used the substances they reported having had contact with and when they were admitted to the rehabilitation center.

Classifications and scores

Each answer to the questionnaires had a specific value, and they were summed for a final score. This score was used to classify the patient into the referred categories, such as ADHD or non-ADHD, for instance, following the instructions of the questionnaire. The score was also used as an evaluation of frequency of symptoms of ADHD or severity of drug use or dependence. Therefore, patients were classified as ADHD or non-ADHD, as well for their subtypes; and as a user, dependent or non-user of each studied substance. They also received a score of ADHD symptom frequency and drug use or dependence severity. The age at first use of substance and age on admission were also used for comparison.

According to the classification received, patients were divided into groups. Then, the statistic comparison of these groups was carried out. In addition, scores and ages were also used for correlations.

Statistical analysis

The two-tailed Fisher's exact test was used to compare the presence of use and dependence on substance in ADHD and non-ADHD groups, as well to compare the number of cocaine dependent individuals and the number of individuals dependent on other drugs.

The Student t test was used to compare the severity of drug use between ADHD and non-ADHD users, as well as for the ages at first use of the substance and age on admission. The effect size was analyzed using Cohen's d coefficient for continuous variables (0.2 – weak effect; 0.5 – moderate effect; and 0.8 – strong effect).

The degree of correlation between the variables was calculated using Pearson's correlation, to compare the score in ARSR-18 and the age at first use of substance, and to correlate age at first use of substance and age on admission and age at first use of substance and prior use severity. P values of less than 0.05 were considered statistically significant. *SPSS 21*, *GraphPad* and *Microsoft Office Excel*[®] were used for the analysis.

RESULTS

Of the 80 patients, 49 (61.25%) were classified as having clinical findings suggestive of ADHD. Seventy-two patients had dependence on other drugs as opposed to only alcohol and were considered polydrug users, but there was no statistical difference between ADHD and non-ADHD populations ($p = 0.0501$). The drugs with the greatest and smallest number

of users were alcohol and cocaine, respectively. This was true for the population with ADHD and the population without ADHD (Table 1), and a similar result was observed for populations with different subtypes of ADHD (Table 2). Also, no difference between the two groups (predominantly attention deficit or predominantly hyperactivity/impulsivity) was found in relation to number of users and type of drugs (Table 2). The drugs with the greatest and smallest number of dependents were cocaine and cannabis, respectively, a pattern that was repeated in all the populations. Cocaine had the highest percentage of dependent users (Table 1). Of the patients who had had at least occasional contact with cocaine, 77.78% developed dependence, while for the other drugs considered together, the corresponding figure was 40.5% ($p < 0.0001$). There was no statistically significant difference in the frequency of substance use and dependence between men and women.

The mean age of the patients admitted to the therapeutic communities was 32.63 ± 9.718 years. The patients had diverse social origins and educational or economic levels.

The difference of economic settings of the patients were reflected in their ability to acquire the substance and their possible enrollment in criminal activities. Some patients were in rehabilitation under judicial sentence. A previous diagnosis of ADHD or treatment was not referred to by the patients. Therefore, this study is not able to assess a different drug addiction prognosis in the treatment of ADHD patients.

Age at first use of cocaine and its derivatives was lower among the ADHD population ($p = 0.033$, Cohen's $d = 0.64$), as was age on admission to rehabilitation ($p = 0.004$, Cohen's $d = 0.67$) (Table 3). In the ADHD population evaluation, there was an inverse correlation between age at first use of cannabis and cannabis use score ($r = -0.350$, $p = 0.017$) and cocaine use score ($r = -0.318$, $p = 0.035$). These results were not observed in the group without ADHD. The age at their first contact with alcohol was lower for men than for women ($p = 0.008$; Cohen's $d = 0.89$). No differences were found in the mean age on admission to rehabilitation and mean age at first substance use between ADHD subtypes (Table 4).

Table 1. Substance use and dependence among patients with and without ADHD.

Variable	Substance use			Substance dependence		
	ADHD	non-ADHD	p	ADHD	non-ADHD	p
Tobacco	45	28	1	15	12	0.4766
Alcohol	48	31	1	27	15	0.3913

Table 4. Age on admission and at first use by ADHD subtype.

Variable	ADHD – HI* (n)	ADHD – IN** (n)	p
Age on admission	31.25 ± 8.36 (24)	29.26 ± 8.81 (23)	0.431
Age at first use			
Tobacco	14.46 ± 2.58 (22)	12.82 ± 3.56 (21)	0.88
Alcohol	14.71 ± 3.56 (24)	14.32 ± 1.86 (23)	0.64
Cannabis	15.76 ± 3.77 (21)	15.43 ± 2.09 (21)	0.725
Cocaine	17.52 ± 3.24 (21)	16.94 ± 3.33 (17)	0.586

ADHD: attention deficit and hyperactivity disorder; *characterized predominantly by hyperactivity and impulsivity; **characterized predominantly by inattention.

There was a correlation between a higher score in the assessment of DSM-IV-TR criteria A (ASRS-18) – ADHD symptoms frequency and age of first use for all the substances studied [tobacco ($r = -0.254$; $p = 0.029$), alcohol ($r = -0.242$; $p = 0.032$), cannabis ($r = -0.337$; $p = 0.001$) and cocaine ($r = -0.432$; $p < 0.001$)] and between frequency of ADHD symptoms and age on admission ($r = -0.370$; $p = 0.001$).

DISCUSSION

Of the 80 patients in rehabilitation, 49 (61.25%) had clinical findings compatible with a diagnosis of ADHD, a value significantly above the estimated global prevalence of 5.3%¹². This is compatible with the results reported by Ballon et al.¹³, who assessed 77 patients and found a higher prevalence of ADHD in cocaine dependent individuals than in controls.

As expected, because all the patients were in rehabilitation for chemical dependence, there was no statistically significant difference in the number of patients who had had some type of contact with substances and the number who developed severe substance use disorder, *i.e.*, dependence, as a result of this contact. There was also no difference in occasional substance use and dependence (substance use disorder) between the different subtypes of ADHD, nor in the ages at first use of substance or age on admission. This finding is different from that reported by De Alwis et al.¹⁴, who found in a study of 33,588 patients from the population at large that the impulsive subtype of ADHD individuals had a greater tendency to use substances and develop dependence.

No statistically significant correlation between a higher score in ASRS-18 and severity of substance use disorder assessed by the application of ASSIST was observed for any of the substances individually. This may indicate that a patient with more frequent symptoms of ADHD does not necessarily progress to more frequent or harmful and incapacitating substance use, or that the ASRS-18 or ASSIST results may not be suitable to set this correlation. In contrast to our findings, Upadhyaya et al.¹⁵ found a positive correlation between the number of symptoms of ADHD and severity of tobacco, alcohol and cannabis use in a sample of 334 university students.

Despite this apparent lack of an association between ADHD and severity of substance use in the present study, there was a significant difference in age at first use of cocaine between groups with and without ADHD. Corroborating this finding, Dunne et al.¹⁶ found a lower age at first use of cocaine among patients with ADHD in a study of 941 substance users, and Carroll et al.¹⁷ reported a similar finding in a study of 298 patients undergoing treatment for cocaine dependence.

In contrast, the lack of any association between age at first use of the other substances and ADHD may indicate that in this population other factors determine age at first use of tobacco, alcohol and cannabis. The results for alcohol and cannabis in the present study agree with those reported

by Galéra et al.⁵ in a study of risk factors for substance use among 1,103 youths, where they found that the association between childhood attention problems and substance use is confounded by a range of other factors. However, our findings are different from those reported by Bidwell et al.⁷, who found a lower age at first use of cannabis in patients with ADHD in a study of 376 undergraduates. Dunne et al.¹⁶ also found differences in the age at first use of tobacco, alcohol and cannabis between groups with and without ADHD. Despite the conflicting results, the present study found an inverse correlation between the frequency of ADHD symptoms and age at first use of all the substances studied. This could indicate that among patients treated in therapeutic communities, those with more frequent ADHD symptoms may start to use tobacco, alcohol, cannabis and cocaine earlier than patients without any or less frequent symptoms of ADHD. A larger sample or a sample consisting of patients with a higher degree of dependence might produce results similar to those reported in other studies.^{16,18}

In the ADHD patients in therapeutic communities, a lower age at first use of cannabis in patients with ADHD appears to lead to heavier use of cannabis as well as cocaine. These correlations are specific to the ADHD group, once they were not identified in the group without ADHD or in the overall group. This finding was also reported by Galéra et al., who established a correlation between early exposure to cannabis and use of the substance at an older age. In addition to the pathophysiological mechanism, sociocultural factors associated with early cannabis users may favor heavier use of cocaine and its derivatives⁵. Despite being the drug to which the fewest patients had a history of exposure, cocaine caused the most dependence (substance use disorder) in the patients investigated. Compared with all the other drugs, cocaine created a statistically significantly higher number of dependent users.

Early use of cocaine and its derivatives may be the reason why patients with ADHD in the therapeutic communities had a lower age at admission. Although there was no difference in the percentage of users who became dependent between the populations with and without ADHD, the fact that patients with ADHD had earlier contact with cocaine makes them more susceptible to dependence at a younger age, which in turn may mean that they are admitted to rehabilitation earlier. Carroll and Rounsaville¹⁷ also found that patients with ADHD are admitted for treatment for cocaine dependence earlier but, unlike the present study, also found heavier cocaine use in patients with ADHD.

In the population studied here, there was a high prevalence of ADHD compared to the general population. In addition, individuals with ADHD were found to have different patterns of drug addiction behavior; such as the age at first use of cocaine, age on admission to rehabilitation, connection between early use of cannabis and severity of cocaine use at later ages. For ADHD patients in therapeutic communities,

earlier use of cannabis may have led to heavier use of cannabis and cocaine at a later age. In these patients, regardless of the specific cause, the occurrence of ADHD set a lower age on admission for rehabilitation. This characteristic may be explained by the earlier contact with the drug that caused the most dependence, cocaine. However, ADHD subtypes do

not seem to progress to differences in the patterns referred to. In ADHD patients, correlation between the severity of cocaine use and a lower age at first contact with cannabis may justify the monitoring of ADHD youth in order to avoid the contact with cannabis, mainly in social standards similar to those shown by the patients assessed by this study.
