ABSTRACT

Objective: The objective of this study was to determine the indications, utility, advantages and surgical approach for the anteromedial thigh (AMT) flap. **Materials and Methods:** We reviewed the records of the patients in whom the AMT flap was used for head and neck reconstruction. We use an anterior approach to harvest the anterolateral thigh (ALT) flap with a non-committal straight line incision. This preserves both ALT and AMT flap territories intact, and further decision is based on the intraoperative anatomy of perforator and pedicle. The ALT flap was usually used as the first choice when available and suitable. **Results:** Free AMT skin flaps were harvested in 24 patients. All flaps were used for the head and neck reconstruction. Two flaps had marginal flap necrosis. One flap was lost due to venous thrombosis. **Discussion:** The thigh is an excellent donor site as it has large available skin territory, expendable lateral circumflex femoral artery system and low donor-site morbidity. The ALT flap is the most commonly used flap for reconstruction of soft-tissue defects. However, it is characterised by variable vascular pedicle and perforator anatomy. The AMT flap is an excellent alternative when the ALT flap is not available due to variable perforator anatomy, injury to perforator, when an intermediate thickness is needed between distal and proximal thigh or a chimeric flap is needed. **Conclusion:** The AMT flap offers all the advantages of the ALT flap without increasing donor-site morbidity. The anterior non-committal approach keeps both the ALT and the AMT flap options viable.

KEY WORDS

Anteromedial thigh perforator flap; chimeric flaps; freestyle perforator flap

INTRODUCTION

In 1984, Song *et al.*^[1] first described the anterolateral thigh (ALT) flap based on perforators of descending branch of the lateral circumflex femoral artery (LCFA).

In the same year, they have also first reported the anteromedial thigh (AMT) flap.^[1]

At present, the ALT flap is a workhorse flap for soft-tissue reconstruction of regional as well as distant defects. We analysed the departmental database and hospital electronic medical records with the purpose of reviewing the AMT flap in terms of its indications, vascular anatomy and surgical approach.

MATERIALS AND METHODS

Among the 2000 reviewed free flaps operated at a tertiary care centre for cancer management from January 2012 to December 2015, 810 patients of free thigh perforator flaps for reconstruction of defects in the head and neck region were reviewed. Of these, 782 were free ALT flaps, 20 were free AMT flaps, 4 were free tensor fasciae latae (TFL) flaps and 4 were chimeric AMT-ALT flaps. Thus, a total of 24 AMT skin flaps were harvested which are included for further analysis. A retrospective review of database is performed with respect to demographics, reasons for choosing AMT, average size of flap, modifications, complications and success rates.

Operative technique

The axis of ALT flap is marked by a line joining the anterior superior iliac spine (ASIS) and supero-lateral border of the patella on the thigh. The axis of AMT flap is marked by another line joining the ASIS and superomedial border of patella. A hand-held audio Doppler 8 MHz was done to scan for perforators pre-operatively in the ALT and AMT flap territory around the midpoint of two axes lines; no other imaging modality was employed for logistical reasons.

The anterior sub-fascial approach was used for flap harvest. We use and propose a non-committal straight line incision at the junction of ALT and AMT flap territory for the harvest of a thigh flap [Figure 1]. The incision is deepened to deep fascia of the thigh. The ALT flap is our first choice. If a suitable ALT perforator is not identified, the incision can be extended proximally or distally to increase the area of search; this most often yields a perforator. Simultaneously or in sequence, a search for AMT perforator is made on the medial side of flap through the same incision. Once the sizable perforator is located, a free-style skin flap is harvested from the antero-medial thigh. The perforator is dissected either through the muscle or through its course within a septum to the source vessel until the adequate pedicle length and size of the vessels for a safe anastomosis are achieved. The free-style perforator flap dissection is then

completed, and the flap is transferred into the defect in usual fashion [Figure 2].

RESULTS

In all 24 patients, AMT flaps were used as free flaps for soft-tissue reconstruction of post-cancer excision defects of the head and neck region. Seventeen patients were male and seven were female. Average flap size was 12–20 cm × 6–7.5 cm. The reasons for choosing the AMT flap were as follows: there was no sizeable/suitable ALT perforator in 19 patients. There was an injury to ALT perforator in one patient. Four patients had large composite multiplanar defects following the resection of head and neck tumour. They were reconstructed using a chimeric-free ALT plus AMT flaps [Figure 3].

Fifteen flaps were harvested on a single perforator. There were two septocutaneous perforators in seven flaps and three septocutaneous perforators in two flaps. Of the 24 flaps, 18 had septocutaneous perforators while remaining 6 had single perforator with musculocutaneous course.

The donor vessel dissection was done until the adequate pedicle length and size for safe anastomosis were achieved. The donor vessels were LCFA in 14 patients, its descending branch in 6, deep femoral artery in 2 and superficial femoral artery in 2 patients.

Donor site needed skin grafting in three patients of chimeric ALT with AMT flap harvest; remaining donor sites were primarily closed [Figure 4].

Figure 2: (a) Perforator for anterolateral thigh flap was absent. (b) Septocutaneous perforator for anteromedial thigh flap (arrow) was identified on medial flap. (c) Perforator to source vessel – lateral circumflex femoral artery (arrowhead) dissection was done. (d) Anteromedial thigh flap after completion of harvest

(b) Intra-operative image showing perforator (white arrow) arising from superficial femoral vessels (black arrow). (c) 2-year post-operative image – well-settled flap. (d) 2-year post-operative image – donor-site scar

Two patients had re-exploration for venous congestion. Of the two, one flap was salvaged. One flap was lost secondary to orocutaneous fistula. Orocutaneous fistula was a consequence of dehiscence of the flap inset secondary to flap edge necrosis. One patient with chimeric flap developed partial necrosis of flap which was managed conservatively by the secondary suturing.

The overall success rate was 95.83% (23 out of 24).

DISCUSSION

At present, the goal of reconstruction is not only to achieve optimal functional and aesthetic outcome but also to minimise the donor-site morbidity. Therefore, the selection of the ‘right’ flap is imperative because an inappropriate choice may not achieve the desired result, no matter how meticulous the surgical execution.^[2]

The introduction of the perforator flap concept and free-style perforator flap technique as described by Wei and Mardini^[3] has actually resulted into achieve this goal to a certain extent. The thigh is one such donor site which provides ample of tissue bulk and skin paddle for the reconstruction of soft-tissue defects. The ALT flap is workhorse flap for soft-tissue defects by virtue of its versatility.

However, its main limitation is variable perforator and pedicle anatomy. In 2% of patients, ALT perforator may not be suitable for flap harvest.^[4] Kimata *et al.*^[5] demonstrated in their initial report that there was no perforator found in 4 of the 74 patients (5.4%). However, the percentage of having no perforator is stated to be less (0.89% [6/672],^[6] 1.37% [6/439],^[7] 1.45% [1/69]^[8] and 1.8% [3/168]^[9]) in various other reports. Occasionally, there can be injury to ALT perforator during dissection, which renders the inability to harvest the ALT flap.

Hence, it is essential to have an alternative flap as a backup plan for successful reconstruction. Simply turning to the other side of the thigh or another donor site will increase the morbidity caused by donor sites.

The perforator flap of the adjacent region becomes the first alternative choice because it provides the same quality and function as the initially planned. The perforasome theory by Saint-Cyr supports the use of the AMT flap when the ALT flap is not available.^[10] The AMT flap has relatively hairless skin compared with the skin of the ALT

flap. The thickness of the thigh is not the same in all parts. The proximal thigh is usually much thicker as compared to rest of the thigh including AMT. In a scenario where an AMT perforator is suitable and thickness matches that of the defect compared to a proximal ALT/TFL perforator with much more thickness or a distal ALT perforator in a thinner part of the thigh, we prefer to harvest the AMT as a matter of choice. However, the AMT flap is more challenging in the sense that perforators have multiple variations and may lead to various source vessels.^[11,12] Despite the anatomical variations, the perforator can be visually identified first followed by elevation of the flap making this a reliable alternative.^[12,13]

The perforator of the AMT flap could arise anywhere from the femoral artery, the LCFA, the medial or lateral descending branch of the LCFA, the innominate branch or from a minor muscle branch to the rectus femoris muscle.^[11,12,14,15]

If there is no suitable perforator in the ALT flap region, the TFL flap based on perforator leading to the transverse branch can also be planned.^[16,17] However, the initial design of the ALT flap frequently involves this region not sparing enough skin flaps to be used. Furthermore, the pedicle length TFL flap is short. The AMT flap is thinner and more pliable than the TFL flap, and these characteristics are specifically important in the reconstruction of the head and neck region.^[18]

Large defects of the head and neck region are challenging to reconstruct as there may be a three-dimensional requirement of both the volume and the multiple surfaces for oral lining and external skin.^[19] In these situations, the chimeric ALT flap is particularly versatile. As the LCFA gives off the various branches, multiple components can be harvested based on the main pedicle.^[20]

Chimeric flaps (ALT with AMT) are used with each paddle based on separate perforators.^[21] This versatility facilitates in setting of the flap to the complex three-dimensional defects. It allows the provision of multiple tissue components as a single yet comprehensive unit. Wei *et al.*^[22] have elegantly shown to be an 'ideal' attribute of the thigh region.

If a single 'mother' vessel serves all the independent portions of a chosen combined free flap, then only a single recipient site may be required for revascularisation. This is most advantageous if there is a paucity of recipient

vessels, such as after bilateral radical neck dissection, post-radiation neck, recurrent lesions and a single-vessel lower extremity.^[23]

CONCLUSION

The AMT flap offers all the advantages of the ALT flap without increasing the donor sites. We suggest a non-committal straight line anterior approach to harvest a thigh flap. The AMT flap is a good alternative to the ALT flap when suitable ALT perforator is not present or injured. The chimeric AMT flap along with the ALT flap is one of the most suitable options to reconstruct large complex soft defects of the head and neck region.
